PR.438

Figure 20-19.—Positioning of the connector cord.

PR.437

Figure 20-18.—Stowage of canopy.

over the locking cone on the spring baseplate. Compress the pilot parachute fully, remove the guide tube, and insert the pilot parachute temporary locking pin into the locking cone hole.

S-fold the pilot parachute connector cord under the kickplate on the helper's side. The connector must exit from the rear of the kickplate. Fold the excess withdrawal line, if any, under the kickplate, as shown in figure 20-19.

Place the pilot parachute kickplate on top of the canopy peak. Tuck the pilot parachute cloth under the pilot parachute crown and place the pilot parachute on top of the kickplate. The withdrawal line must exit from the rear of the helper's end flap.

Remove the temporary locking pin on the helper's side and pull the end flap over the compressed pilot chute. Route the withdrawal line out the rear of the container. Remove the grommet side flap from the locking cone and place the grommet over the locking cone. Place the end tab over the locking cone and reinsert the temporary locking pin. Insert the riser protective flaps into the container using a packing fid.

Insert the ripcord anchor plate through the webbing loop on the end flap. The manual ripcord cable must pass over the loop. The helper holds the end tab over the locking cone on the withdrawal line end of the container and the packer removes the temporary locking pin. The packer will position the anchor plate over the locking cone and insert the temporary locking pin; removal of the pilot parachute temporary locking pin can now be made.

Route the ripcord pin line through the alinement ring on the end flap. Insert the curved ripcord pin through the eye on the end of the manual ripcord cable. The helper must insert

11272

a curved ripcord pin into the locking cone containing the anchor plate as the packer removes the temporary locking pin. Insert a straight ripcord pin into the second locking cone in the same manner.

Safety-tie the straight ripcord pin by looping a length of size A nylon thread, unwaxed, under the ripcord pin. Secure the pin by tying 3 or 4 half-hitches around the ripcord cable.

Route the locking lanyard through the alinement ring. Place the locking ring over the locking cone and insert the locking pin into the locking cone.

Safety-tie the locking pin by passing a length of unwaxed size A nylon thread, single, under the end of the pin and through the loop formed at the back of the pin. Tie the ends with a surgeon's knot followed by a square knot. (See fig. 19-22.)

For an illustration of proper closure of the parachute assembly container, see figure 20-20.

Close the ripcord protector flap, remove the container from the stand, and attach the four container spring opening bands (two on each end of the container).

Crimp the hook at the container end to the eyelet. Do not crimp the flap end hook. Position the risers on top of the container and mate the hook and pile tape patches.

Fill out and sign the parachute history card and the parachute record card. Insert GND/AIR emergency code form, and the parachute record card, into the packing data card pocket located on the ripcord pin protector flap.

PR.440
Figure 20-20.—Proper closure of container.

NOTE: Collateral duty inspection is a mandatory requirement in rigging and packing procedures. As each phase is completed, all work must stop until a collateral duty inspector has performed the inspection.

11279

by L_1 covers the upper half of the tube's neck and is in opposition to the flux around the electron beam. The magnetic flux covering the lower half of the tube's neck is established by the current flowing through L_2 and is traveling in the same direction as the lines of force around the electron beam; thus they are aiding or reinforcing the flux in the lower half. The flux's resultant force on the electron beam is in an upward direction; thus, the beam will be deflected in an upward direction. Therefore, it can be seen that an electron moving perpendicular to a magnetic field is deflected at right angles to its path and to the field.

If the direction of current flow through the windings L_1 and L_2 is reversed, the direction of the flux set up by each will also be in the opposite direction. With the magnetic flux around the beam unchanged, the resultant force acting on the electron beam will also be in the opposite direction. Therefore, the electron beam will be deflected in a downward direction.

The speed at which the electron beam will be deflected across the screen of the CRT will be dependent upon the rate of change of current flow in the windings. The maximum distance that the electron beam will be deflected will be dependent upon the amount of magnetic flux established by the coils.

Part (B) of figure 17-9 is an illustration of a set of coils similar to the coils illustrated in part (A) except that they are oriented to deflect the beam in the horizontal plane. Deflection of the electron beam is accomplished by coils L_3 and L_4 in a manner similar to the deflection in the vertical plane by coils L_1 and L_2. As illustrated, the electron beam is deflected to the left; but if the current through the coils is reversed in direction, the beam will be deflected in the opposite direction across the screen of the CRT.

Thus far the vertical and horizontal deflection coils have been discussed separately. However, if they were wound on the same iron core and energized simultaneously, the electron beam could be deflected in directions other than in the vertical and horizontal plane. The operation of the stationary electromagnetic yoke is based on this principle.

Figure 17-10 is used to further illustrate the operation of the deflection coils and how the electron beam can be deflected in various directions. The electron beam is coming out of the paper and the amplitude of the current through each coil is the same for each illustration in figure 17-10.

When current flow through L_1, L_2, L_3, and L_4 is as shown in figure 17-10 (A), the beam will be deflected in the direction indicated. The direction of the movement is the result of the vertical and horizontal forces acting on the electron beam which is illustrated by broken lines. Since each of the forces is equal, the resultant force is 45° from or halfway between the two.

If current continues to flow in the same diration in L_1 and L_2 but is reversed in the horizontal coils L_3 and L_4, the effect will be as shown in (B) of figure 17-10.

With the current continuing to flow in the same direction through L_3 and L_4 but reversed in L_1 and L_2, the deflection of the electron beam will be in the direction as illustrated in (C) of figure 17-10. Reversing the current through L_3 and L_4 again, but leaving L_1 and L_2 unchanged, will cause the electron beam deflection to advance another 90° around the screen of the CRT. (See fig. 17-10 (D).)

In summary, it should be recalled that current flow in the vertical deflection coils produced either an upward or a downward deflection of the electron beam, depending on the direction of current flow. The same was true of the left or right deflection produced by current in the horizontal deflection coils. When the current flow through the two sets of deflection coils was equal, the deflection of the electron beam was 45° from the vertical and horizontal planes. However, the quadrant in which the beam was deflected depended on the direction of current flow through the coils and not the amplitude.

It should be noted that as the current in each set of coils was reversed consecutively, one after the other, the trace produced by the electron beam advanced around the screen of the CRT by an angular amount of 90°. However, to have one type of scope presentation (a PPI-type scan), the trace on the screen must appear to be continuously rotating about the center axis of the CRT. This can be accomplished by varying the amplitude of the deflection currents applied to each set of deflection coils at a sine-wave rate, but the amplitude variations in one pair of coils must be 90° out of phase with those in the other pair.

The synchro resolver, sometimes called a sweep resolver, is normally used in airborne radar equipment to provide currents of the

ABSTRACT - To aid enlisted Navy men in preparing for advancement to Electrician's Mate 3 or 2, this training course was prepared by the Navy Training Publications Division. Chapters are: (1) Advancement, (2) The 3-M System, (3) Electrical Cables and Accessories, (4) Shipboard Lighting, (5) Searchlights, (6) Maintenance of Motors and Generators, (7) Batteries, (8) Protective Devices, (9) Control Devices, (10) Small Craft Electrical Systems, (11) Power Distribution, (12) Electric Auxiliaries, (13) Gyrocompasses, (14) Electric Propulsion, and (15) Records and Reports. A list of 33 training films is appended. (GB)

BUREAU OF NAVAL PERSONNEL

NAVY TRAINING COURSE NAVPERS 10546-B

PREFACE

This training course is written to aid enlisted men in the U. S. Navy and Navy Reserve in preparing for advancement to the rate of Electrician's Mate 3 or 2.

The subjects with which the striker or EM3 must be familiar before he can qualify for advancement to Electrician's Mate 3 or 2 are outlined in the Manual of Qualifications for Advancement in Rating. This training course contains information on each examination, and, insofar as practicable, information on each practical factor. Because examinations for advancement in rating are based on these qualifications, interested personnel should refer to them for guidance (the LATEST qualifications should always be consulted).

The Electrician's Mate 3 & 2 training course was prepared by the U.S. Navy Training Publications Division, of the Naval Personnel Program Support Activity, Washington, D.C., which is a field activity of the Bureau of Naval Personnel. Technical assistance was provided by the Bureau of Naval Personnel, the Naval Ship Systems Command, and the Service School Command, U.S. Navy Training Center, Great Lakes, Illinois.

THE UNITED STATES NAVY

GUARDIAN OF OUR COUNTRY

The United States Navy is responsible for maintaining control of the sea and is a ready force on watch at home and overseas, capable of strong action to preserve the peace or of instant offensive action to win in war.

It is upon the maintenance of this control that our country's glorious future depends; the United States Navy exists to make it so.

WE SERVE WITH HONOR

Tradition, valor, and victory are the Navy's heritage from the past. To these may be added dedication, discipline, and vigilance as the watchwords of the present and the future.

At home or on distant stations we serve with pride, confident in the respect of our country, our shipmates, and our families.

Our responsibilities sober us; our adversities strengthen us.

Service to God and Country is our special privilege. We serve with honor.

THE FUTURE OF THE NAVY

The Navy will always employ new weapons, new techniques, and greater power to protect and defend the United States on the sea, under the sea, and in the air.

Now and in the future, control of the sea gives the United States her greatest advantage for the maintenance of peace and for victory in war.

Mobility, surprise, dispersal, and offensive power are the keynotes of the new Navy. The roots of the Navy lie in a strong belief in the future, in continued dedication to our tasks, and in reflection on our heritage from the past.

Never have our opportunities and our responsibilities been greater.

USAFI TEXTS

United States Armed Forces Institute (USAFI) courses for additional reading and study are available through your Educational Services' Officer.* The following is a partial list of those courses applicable to your rate:

D290	Physics I
C781	Fundamentals of Electricity
C858	The Slide Rule
D435	Plane Trigonometry

*"Members of the United States Armed Forces Reserve components, when on active duty, are eligible to enroll for USAFI course, services, and materials if the orders calling them to active duty specify a period of 120 days or more, or if they have been on active duty for a period of 120 days or more, regardless of the time specified on the active duty order."

11286

CHAPTER 1

ADVANCEMENT

This training course is designed to aid you in preparing for advancement to EM 3 and EM 2. There are many requirements for advancement, and they will be discussed in this chapter. The professional (technical) requirements for advancement to EM3 and EM2 used as a guide in the preparation of this course are listed in group VII of the Manual of Qualifications for Advancement in Rating, NavPers 18068-B.

Chapter 2 of this course discusses the maintenance and material management (3-M) system. The 3-M system will be in use on all ships of the Navy. This chapter shows and explains the cards and forms you will be using in the 3-M system.

Chapter 3 of this training course describes the types, uses, and installation of shipboard electric cable and accessories. It includes the various tests and inspections necessary for the proper maintenance and repair of electric cables.

Chapter 4 explains the principles of light to familiarize the EM striker or EM 3 with the fundamentals and terminology of electric lighting. It describes the types of lamps and light fixtures used on naval vessels, and the practical methods of calculating illumination requirements. Lighting distribution systems are explained, including the maintenance of lighting installations and the safety precautions to be observed when working with this equipment.

Chapter 5 covers the types of Navy searchlights. It describes the construction, operation, and maintenance of these searchlights including the safety precautions involved.

Chapter 6 deals with the maintenance of motors and generators. It acquaints the Electrician's Mate with the preventive and corrective maintenance procedures used by the Navy to obtain optimum performance of these machines.

Chapter 7 presents the maintenance of batteries. It describes the types, characteristics, and installation of dry batteries and storage batteries used in the Navy. The maintenance, troubles, and storage of batteries are presented in detail, including the safety precautions to be observed when working with batteries.

Chapter 8 covers the protective devices used in electrical circuits and equipment. It includes a description of the construction and function of the various types of fuses, switches, relays, and circuit breakers. A description is also given of troubleshooting single-phase and three-phase circuits.

Chapter 9 presents control devices, which include rheostats, electric brakes, and contactors. It includes a description of the construction, operation, and maintenance of these devices. Also included is an analysis of circuit diagrams of d-c and a-c motor starters.

Electrical systems in small craft are discussed in chapter 10. This discussion includes the engine starting systems of diesel powered boats and a description of the lighting systems. This chapter also briefly covers the ignition systems of gasoline engines.

Chapter 11 covers the electric power distribution systems installed in naval vessels including the methods of interconnecting the various switchboards and the operation of automatic bus transfer equipment. It describes cross-plant (parallel) and split-plant operation and operation under casualty conditions.

Chapter 12 describes electric auxiliaries, which includes degaussing installations, anchor windlass, electric elevators, electrohydraulic steering gear, and electric galley equipment.

Chapter 13 discusses gyrocompasses and chapter 14 discusses a-c and d-c electric propulsion installations.

11287

Chapter 15 discusses engineering records and technical publications that concern the Electrician's Mate.

The remainder of this chapter contains information that will help you in preparing for advancement. Study this chapter carefully before beginning intensive study of the remainder of this training course.

THE ENLISTED RATING STRUCTURE

The two main types of ratings in the present enlisted rating structure are general ratings and service ratings.

GENERAL RATINGS identify broad occupational fields of related duties and functions. Some general ratings include service ratings; others do not. Both Regular Navy and Naval Reserve personnel may hold general ratings.

SERVICE RATINGS identify subdivisions or specialties within a general rating. Although service ratings can exist at any petty officer level, they are most common at the PO3 and PO2 levels. Both Regular Navy and Naval Reserve personnel may hold service ratings.

THE ELECTRICIAN'S MATE RATING

Almost every operation aboard ship, routine or emergency, requires electric power for its accomplishment. A ship that has lost electric power has lost her capability as a fighting unit. As a member of the EM group, E division, engineering department, you will be directly concerned with the operation and maintenance of the equipment used to generate and distribute electric power. You will also be concerned with the maintenance and repair of the many lighting and power circuits and equipments throughout the ship.

The EM rating is a general rating only. Electrician's Mates are included in the personnel allowance for practically all Navy ships, including repair ships and tenders. Classification codes for the ratings are listed in group VII of the Manual of Navy Enlisted Classifications, NavPers 15105. Included are classification codes for jobs that require special training such as harbor defense electrician, minesweeping electrician, motion picture projection equipment repairman, ranging and deperming (degaussing) electrician, and gyrocompass electrician.

The Electrician's Mate must have a good working knowledge of the basic principles of electricity and mathematics. If you are lacking in these areas, the courses listed in the front of this training course will be helpful. You will gain the necessary practical experience for advancement through performance of your daily duties. Increasing your technical knowledge, however, will require some reading and studying in your spare time.

Upon advancement to EM 3 you will be graded on your leadership and supervisory ability as well as your ability to perform your technical duties. Study the leadership principles and techniques discussed in Military Requirements for Petty Officers 3 & 2. Additional material concerning leadership for petty officers is available to you as a result of the Navy leadership program. As you study the material containing leadership traits, keep in mind that probably none of our most successful leaders possessed all of these traits to a maximum degree, but a weakness in some traits was more than compensated for by strength in others. Critical self-evaluation will enable you to identify the traits in which you are strong, as well as those in which you are weak. Leadership principles can be taught, but a good leader becomes a good leader only through hard work and practice. Your success as a leader will be judged for the most part by how well you inspire others to learn and perform, and by personal example.

ADVANCEMENT IN RATING

Some of the rewards of advancement in rating are easy to see. You get more pay. Your job assignments become more interesting and more challenging. You are regarded with greater respect by officers and enlisted personnel. You enjoy the satisfaction of getting ahead in your chosen Navy career.

But the advantages of advancing in rating are not yours alone. The Navy also profits. Highly trained personnel are essential to the functioning of the Navy. By each advancement in rating, you increase your value to the Navy in many ways. You become more experienced in military leadership and better trained as a specialist in your own rating. Therefore, you become more valuable as an experienced Petty Officer, who can train others, and thus make far-reaching contributions to the entire Navy.

11288

11288

HOW TO QUALIFY FOR ADVANCEMENT

What must you do to qualify for advancement in rating? The requirements may change from time to time, but usually you must:

1. Have a certain amount of time in your present grade.
2. Complete the required military and occupational training courses.
3. Demonstrate your ability to perform all the PRACTICAL requirements for advancement by completing the Record of Practical Factors, NavPers 1414/1. In some cases the Record of Practical Factors may contain the old form number, NavPers 760, until stocks are exhausted.
4. Be recommended by your commanding officer, after the petty officers and officers supervising your work have indicated that they consider you capable of performing the duties of the next higher rate.
5. Demonstrate your KNOWLEDGE by passing a written examination on (a) military requirements and (b) occupational qualifications.

Some of these general requirements may be modified in certain ways. Figure 1-1 gives a more detailed view of the requirements for advancement of active duty personnel; figure 1-2 gives this information for inactive duty personnel.

Remember that the requirements for advancement can change. Check with your division officer or training officer to be sure that you know the most recent requirements.

Advancement in rating is not automatic. After you have met all the requirements, you are ELIGIBLE for advancement. You will actually be advanced in rating only if you meet all the requirements (including making a high enough score on the written examination) and if the quotas for your rating permit your advancement.

HOW TO PREPARE FOR ADVANCEMENT

What must you do to prepare for advancement in rating? You must study the qualifications for advancement, work on the practical factors, study the required Navy Training Courses, and study other material that is required for advancement in your rating. To prepare for advancement, you will need to be familiar with (1) the Quals Manual, (2) the Record of Practical Factors, NavPers 1414/1, (3) a NavPers publication called Training Publications for Advancement in Rating, NavPers 10052, and (4) applicable Navy Training Courses. The following sections describe them and give you some practical suggestions on how to use them in preparing for advancement.

The Quals Manual

The Manual of Qualifications for Advancement in Rating, NavPers 18068B (with changes), gives the minimum requirements for advancement to each rate within each rating. This manual is usually called the "Quals Manual," and the qualifications themselves are often called "quals." The qualifications are of two general types: (1) military requirements, and (2) occupational qualifications.

MILITARY REQUIREMENTS apply to all ratings rather than to any one particular rating. Military requirements for advancement to third class and second class petty officer rates deal with military conduct, naval organization, military justice, security, watch standing, and other subjects which are required of petty officers in all ratings.

OCCUPATIONAL QUALIFICATIONS are requirements that are directly related to the work of each rating.

Both the military requirements and the occupational qualifications are divided into subject matter groups; then, within each subject matter group, they are divided into PRACTICAL FACTORS and KNOWLEDGE FACTORS. Practical factors are things you must be able to DO. Knowledge factors are things you must KNOW in order to perform the duties of your rating.

You are required to pass a Navy-wide military/leadership examination for E-4 or E-5, as appropriate, before participating in the occupational examinations. The military/leadership examinations for both levels are given quarterly. Candidates are requried to pass the applicable military/leadership examination only once. Each of these examinations consists of 100 questions based on Military Standards contained in the Quals Manual and information contained in the Publications listed under Military Requirement in Training Publications for Advancement in Rating, NavPers 10052.

The Navy-wide occupational examinations for pay grades E-4 and E-5 will contain 150 questions related to occupational areas of the EM rating.

If you are working for advancement to second class, remember that you may be examined on third class qualifications as well as on second class qualifications.

11.89
11290

Figure 17-10. —Deflection yoke.

proper value and relationship to produce a rotating sweep.

Figure 17-11 is a schematic of a sweep resolver, the rotor of which is positioned in synchronism with the antenna. The sweep voltage from the sweep generator located in the synchronizer is applied to the rotor winding. The output amplitude and polarity from each of the stator windings will depend upon the relative position of the rotor.

If the antenna is pointing dead ahead at 0 degrees azimuth, the vertical deflection of the electron beam must be maximum upward and the azimuth deflection, zero. At 90° or 270° azimuth, the vertical deflection must be zero and the horizontal deflection maximum either

11291

163

The Quals Manual is kept current by means of changes. The occupational qualifications for your rating which are covered in this training course were current at the time the course was printed. By the time you are studying this course, however, the quals for your rating may have been changed. Never trust any set of quals until you have checked it against an UP-TO-DATE copy in the Quals Manual.

Record of Practical Factors

Before you can take the servicewide examination for advancement in rating, there must be an entry in your service record to show that you have qualified in the practical factors of both the military requirements and the occupational qualifications. A special form known as the RECORD OF PRACTICAL FACTORS, NavPers 1414/1 is used to keep a record of your practical factor qualifications. This form is available for each rating. The form lists all practical factors, both military and occupational. As you demonstrate your ability to perform each practical factor, appropriate entries are made in the DATE and INITIALS columns.

Changes are made periodically to the Manual of Qualifications for Advancement in Rating, and revised forms of NavPers 1414/1 are provided when necessary. Extra space is allowed on the Record of Practical Factors for entering additional practical factors as they are published in changes to the Quals Manual. This Record of Practical Factors also provides space for recording demonstrated proficiency in skills which are within the general scope of the rating but which are not identified as minimum qualifications for advancement.

If you are transferred before you qualify in all practical factors, the NavPers 1414/1 form should be forwarded with your service record to your next duty station. You can save yourself a lot of trouble by making sure that this form is actually inserted in your service record before you are transferred. If the form is not in your service record, you may be required to start all over again and requalify in the practical factors which have already been checked off.

NavPers 10052

Training Publications for Advancement in Rating, NavPers 10052 (revised), is a very important publication for anyone preparing for advancement in rating. This bibliography lists required and recommended Navy Training Courses and other reference material to be used by personnel working for advancement in rating. NavPers 10052 is revised and issued once each year by the Bureau of Naval Personnel. Each revised edition is identified by a letter following the NavPers number. When using this publication, be SURE that you have the most recent edition.

If extensive changes in qualifications occur in any rating between the annual revisions of NavPers 10052, a supplementary list of study material may be issued in the form of a BuPers Notice. When you are preparing for advancement, check to see whether changes have been made in the qualifications for your rating. If changes have been made, see if a BuPers Notice has been issued to supplement NavPers 10052 for your rating.

The required and recommended references are listed by rate level in NavPers 10052. If you are working for advancement to third class, study the material that is listed for third class. If you are working for advancement to second class, study the material that is listed for second class; but remember that you are also responsible for the references listed at the third class level.

In using NavPers 10052, you will notice that some Navy Training Courses are marked with an asterisk (*). Any course marked in this way is MANDATORY—that is, it must be completed at the indicated rate level before you can be eligible to take the servicewide examination for advancement in rating. Each mandatory course may be completed by (1) passing the appropriate enlisted correspondence course that is based on the mandatory training course; (2) passing locally prepared tests based on the information given in the training course; or (3) in some cases, successfully completing an appropriate Class A course.

Do not overlook the section of NavPers 10052 which lists the required and recommended references relating to the military requirements for advancement. Personnel of ALL ratings must complete the mandatory military requirements training course for the appropriate rate level before they can be eligible to advance in rating.

The references in NavPers 10052 which are recommended but not mandatory should also be

11292

studied carefully. ALL references listed in NavPers 10052 may be used as source material for the written examinations, at the appropriate rate levels.

Navy Training Courses

There are two general types of Navy Training Courses. RATING COURSES (such as this one) are prepared for most enlisted ratings. A rating training course gives information that is directly related to the professional qualifications of ONE rating. SUBJECT MATTER COURSES or BASIC COURSES give information that applies to more than one rating.

Navy Training Courses are revised from time to time to keep them up to date technically. The revision of a Navy Training Course is identified by a letter following the NavPers number. You can tell whether any particular copy of a Navy Training Course is the latest edition by checking the NavPers number and the letter following this number in the most recent edition of List of Training Manuals and Correspondence Courses, NavPers 10061. (NavPers 10061 is actually a catalog that lists all current training courses and correspondence courses; you will find this catalog useful in planning your study program.)

Navy Training Courses are designed to help you prepare for advancement in rating. The following suggestions may help you to make the best use of this course and other Navy training publications when you are preparing for advancement in rating.

1. Study the military requirements and the occupational qualifications for your rating before you study the training course, and refer to the quals frequently as you study. Remember, you are studying the training course primarily in order to meet these quals.

2. Set up a regular study plan. It will probably be easier for you to stick to a schedule if you can plan to study at the same time each day. If possible, schedule your studying for a time of day when you will not have too many interruptions or distractions.

3. Before you begin to study any part of the training course intensively, become familiar with the entire book. Read the preface and the table of contents. Check through the index. Look at the appendixes. Thumb through the book without any particular plan, looking at the illustrations and reading bits here and there as you see things that interest you.

4. Look at the training course in more detail, to see how it is organized. Look at the table of contents again. Then, chapter by chapter, read the introduction, the headings, and the subheadings. This will give you a pretty clear picture of the scope and content of the book. As you look through the book in this way, ask yourself some questions: What do I need to learn about this? What do I already know about this? How is this information related to information given in other chapters? How is this information related to the qualifications for advancement in rating?

5. When you have a general idea of what is in the training course and how it is organized, fill in the details by intensive study. In each study period, try to cover a complete unit—it may be a chapter, a section of a chapter, or a subsection. The amount of material that you can cover at one time will vary. If you know the subject well, or if the material is easy, you can cover quite a lot at one time. Difficult or unfamiliar material will require more study time.

6. In studying any one unit—chapter, section, or subsection—write down the questions that occur to you. Many people find it helpful to make a written outline of the unit as they study, or at least to write down the most important ideas.

7. As you study, relate the information in the training course to the knowledge you already have. When you read about a process, a skill, or a situation, try to see how this information ties in with your own past experience.

8. When you have finished studying a unit, take time out to see what you have learned. Look back over your notes and questions. Maybe some of your questions have been answered, but perhaps you still have some that are not answered. Without looking at the training course, write down the main ideas that you have gotten from studying this unit. Don't just quote the book. If you can't give these ideas in your own words, the chances are that you have not really mastered the information.

9. Use Enlisted Correspondence Courses whenever you can. The correspondence courses are based on Navy Training Courses or on other appropriate texts. As mentioned before, completion of a mandatory Navy Training Course can be accomplished by passing an Enlisted Correspondence Course based on the Navy Training Course. You will probably find it helpful to take other correspondence courses, as well as those based on mandatory training courses. Taking a correspondence course helps you to master

11293

the information given in the training course, and also helps you see how much you have learned.

10. Think of your future as you study Navy Training Courses. You are working for advancement to third class or second class right now, but someday you will be working toward higher rates. Anything extra that you can learn now will help you both now and later.

SOURCES OF INFORMATION

Besides training courses, NavPers 10052 lists official publications on which you may be examined. You should not only study the sections required, but should become as familiar as possible with all publications you use.

One of the most useful things you can learn about a subject is how to find out more about it. No single publications can give you all the information you need to perform the duties of your rating. You should learn where to look for accurate, authoritative, up-to-date information on all subjects related to the military requirements for advancement and the professional qualifications of your rating.

PUBLICATIONS YOU SHOULD KNOW

Some of the publications that you will need to study as you prepare for advancement have already been listed in the reading list at the front of this course. The publications listed with NavPers numbers are BuPers publications.

The Naval Ship Systems Command issues a number of publications that will also be helpful to you in studying for advancement.

The Naval Ships Technical Manual is the new title of the former BuShips Technical Manual and is referred to by the new title throughout this training course. This Manual is also undergoing revision which entails several new changes that are explained below. It may be some time before the revision is completed and you may encounter copies that are still titled BuShips Technical Manual but they are the same. The NavShips Technical Manual consists of three volumes as follows:

Volume 1, NavShips 0901-000-0010
Volume 2, NavShips 0901-000-0020
Volume 3, NavShips 0901-000-0030

The NavShips Technical Manual is kept up to date by means of quarterly changes.

In 1963, the Naval Ship Systems Command began to renumber individual chapters in the Manual according to the Navy - Marine Corps Standard Subject Classification System. Under this system, all chapters of the Manual will eventually be part of the 9000 series which identifies ship design and ship's material subject groups. When all chapters have been renumbered to conform to the 9000 series, the old chapter numbers will be eliminated. In the meantime, you will have to consult the cross-reference sheet in the front of the first volume of the Manual for the listing of both the old and new numbers of the various chapters. Some of the old and new numbers have the same positions in the manual while others have changed. For example, the old chapters 60, 61, 62, 63, and 64 are renumbered 9600, 9610, 9620, 9630 and 9640. However, some chapters will be both relocated and renumbered. For example the old chapter 40 will become 9005 and the old chapter 6 will be 9004. The chapters of the NavShips Technical Manual of particular importance to you as an EM are listed in chapter 15 of this training course (listing both the old and new chapter numbers).

The Naval Ship Systems Command Technical News (formerly Bureau of Ships Journal) is a monthly publication with useful articles on all aspects of shipboard engineering. This publication is particularly useful because it supplements and clarifies information contained in the NavShips Technical Manual and also presents information on new developments.

TRAINING FILMS

Training films available to naval personnel are a valuable source of supplementary information on many technical subjects. A selected list of training films that may be useful to you is given in appendix I of this training course. Other films that may be of interest are listed in the United States Navy Film Catalog, NAVWEPS 10-1-777. This catalog, published in 1966, supersedes three earlier publications: the former catalog with the same title but numbered NP 10000-A; the Supplement, NAVWEPS 10-1-772; and the Navy Classified Film Catalog, NP 10001-A.

When selecting a film, note its date of issue listed in the film catalog.

As you know, procedures sometimes change rapidly. Thus some films become obsolete rapidly. If a film is obsolete only in part, it

11294

may still have sections that are useful, but it is important to note procedures that have changed.

SAFETY PRECAUTIONS

After an accident has happened, investigation almost invariably shows that it could have been prevented by the exercise of simple safety precautions which are then posted for future guidance, but which never undo the consequences of the accident that has gone before. Always observe safety precautions and keep accidents from happening.

Always remember that:

1. Electricity strikes without warning.
2. Hurrying reduces caution and invites accidents.
3. Taking time to be careful saves time in the end.
4. Taking chances is an invitation to trouble.
5. If you do not know the safe way, it pays to find out before exposing yourself to danger.
6. Every electrical circuit, with but insignificant exceptions which definitely do not include circuits even as low as 35 volts and possibly even lower, is a potential source of danger and MUST BE TREATED AS SUCH.
7. Except in cases of emergency, never work on an energized circuit. It must be considered that the circuit is energized until a personal check has been made to see that the switch is opened and tagged, and the circuit has been tested with a voltmeter, or voltage tester.

Energized switchboards are a great source of danger. No work shall be undertaken on switchboards (energized or deenergized) without first obtaining the approval of the electrical or engineer officer. The Commanding Officer's approval shall be obtained prior to the commencement of work on an energized switchboard.

Records show that seven out of ten victims of electric shock were revived when artificial respiration was started in less than 3 minutes after the shock. After 3 minutes the chances of revival decrease rapidly.

All shipboard personnel should be made aware of the fact that a victim rendered unconscious by electric shock should receive artificial respiration, and that it should be started in a matter of seconds rather than minutes. To this end the person nearest the victim should start the resuscitation without delay and call or send others for assistance and medical aid. The only logical permissible delay is that required to free the man from his contact with the electricity in the quickest, safest way. This step, while it must be taken quickly, must be done with great care, otherwise there may be two victims instead of one. This should be done in the case of a portable electric tool, light, appliance, equipment, or portable outlet extension by turning off the bulkhead supply switch or by removing the plug from its bulkhead receptacle. If the switch or bulkhead receptacle cannot be quickly located, the suspected electric device may be pulled free of the victim by grasping the insulated flexible cable to the device and carefully withdrawing it clear of its contact with the victim. Other persons arriving on the scene must be clearly warned not to touch the suspected equipment until it is unplugged. Aid should be enlisted to unplug the device as soon as possible. Where the victim is in contact with stationary equipment such as a bus bar or the contacts on a machine, he should be pulled free if the equipment cannot be quickly deenergized, or if considerations of military operation or ship survival prevent immediate shutdown of the circuits. The man can be quickly and safely cleared from his contact with the electricity by carefully applying the following procedures.

To save time, the equivalent of protective insulation for the rescuer must be improvised. For example, instead of taking time to hunt for a pair of rubber gloves for use in grasping the victim, the victim can be safely pulled free if conditions are dry by grasping him by slack in his clothing or by the leather of his shoes. Instead of hunting for a rubber mat on which to stand, such nonconducting materials as deck linoleum, a pillow, blanket, mattress, dry wood, or coil of rope will suffice. In no case during the rescue should any part of the rescuer's person directly touch hull metal or metal structure of furniture.

Additional information on safety is to be found in "Electric Shock-Its Causes and Its Prevention," NAVSHIPS 250-660-42.

RESUSCITATION FOR ELECTRIC SHOCK

The following instructions on resuscitation were furnished by the Bureau of Medicine and Surgery.

11295

Artificial resuscitation after electric shock includes artificial respiration to reestablish breathing, and external heat massage to reestablish heart beat and blood circulation.

To aid a victim of electric shock after removing him from contact with the electricity, immediately apply mouth-to-mouth artificial respiration.

If there is no pulse, immediately apply heart massage also.

Don't waste precious seconds carrying the victim from a cramped, wet, or isolated location to a roomier, dryer, frequented location.

If desired, breathe into victims mouth through a cloth or a handkerchief placed over victim's face. If assistance is available, take turns breathing into victim and in massaging his heart. See figure 1-3, parts 1, 2, and 3.

Cardiac Arrest (Loss of Heart Beat)

If the subject has suffered an electric shock and has no heart beat he will have a cardiac arrest. This can be demonstrated by finding a complete absence of any pulse at the wrist or in the neck. Associated with this the pupils of the eyes will be very dilated, respiration will be weak or stopped. The subject may appear to be dead. Under these circumstances severe brain damage will occur in four minutes unless circulation is reestablished by cardiac massage.

Closed Chest Cardiac Massage

This method has been adopted as practical and can be learned by anyone who is properly instructed, and requires only two hands. The object in closed chest cardiac massage is to squeeze the heart through the chest wall thereby emptying it to create a peripheral pulse. This must be done about 60 times each minute.

DIRECTIONS:

Place subject on his back; a firm surface, such as the deck, is preferred. Expose subject's chest.

Kneel beside victim; feel for lower end of subject's sternum (breastbone); place one hand across breastbone so the heel of hand covers the lower part; place second hand on top of the first so that the fingers point toward neck as in figure 1-3 part 3.

With arms nearly straight, rock forward so that a controlled amount of your body weight is transmitted through your arms and hands to the breastbone. The amount of pressure to apply will vary with the subject. With an adult subject the chest wall should be depressed 2 to 3 inches with each pressure application.

Repeat application of pressure about 60 to 80 times per minute.

An assistant should be ventilating the subjects lungs preferably with pure oxygen under intermittent positive pressure; otherwise with mouth-to-mouth resuscitation. However, closed chest massage will cause some ventilation of the lungs. Therefore, if you are alone you must concentrate on the massage until help can arrive.

Direct other assistants when available to keep checking the patient's pulse. Use the least pressure that will secure an effective pulse beat. The pupils of the victims eyes will become smaller when effective cardiac massage is being performed.

Pause occasionally to determine if a spontaneous heart beat has returned.

Precautions: Make every effort to keep the hands positioned as described in order to prevent injuries to the liver, ribs, or other vital organs. Since the heart cannot recover unless supplied with oxygenated blood it is necessary to accompany cardiac massage with mouth-to-mouth artificial respiration. When there is only one operator the cardiac massage must be interrupted every half minute or so to institute rapid mouth-to-mouth breathing for three or four respirations.

Safety precautions must always be observed by persons working around electric circuits and equipment to avoid injury from electric shock and/or short circuits caused by accidentally placing or dropping a metal tool, ruler, flashlight case, or other conducting article across an energized line. The arc and fire which can be so started on even relatively low voltage circuits may cause extensive damage to equipment and serious injury to personnel.

That the danger of shock from the 450-volt a-c ship's service system is reasonably well recognized by operating personnel is shown by relatively few reports of serious shock received from this voltage despite its widespread use. On the other hand, a number of shipboard fatalities have been reported due to contact with 115-volt circuits. Despite a fairly widespread but totally unfounded popular belief to the contrary, low voltage (115 volts and below) circuits are very dangerous and can cause death where the resistance of the body is lowered by moisture and especially when current passes through the chest.

11296

ARTIFICIAL RESPIRATION

MOUTH-TO-MOUTH OR MOUTH-TO-NOSE RESCUE BREATHING

① **PLACE CASUALTY ON BACK IMMEDIATELY**
DON'T WASTE TIME MOVING TO A BETTER PLACE, LOOSENING CLOTHING, OR DRAINING WATER FROM LUNGS.

② **QUICKLY CLEAR MOUTH AND THROAT**
REMOVE MUCUS, FOOD AND OTHER OBSTRUCTIONS.

③ **TILT HEAD BACK AS FAR AS POSSIBLE**
THE HEAD SHOULD BE IN A "CHIN-UP" OR "SNIFF" POSITION AND THE NECK STRETCHED.

④ **LIFT LOWER JAW FORWARD**
GRASP JAW BY PLACING THUMB INTO CORNER OF MOUTH. DO NOT HOLD OR DEPRESS TONGUE.

⑤ **PINCH NOSE SHUT OR SEAL MOUTH**
PREVENT AIR LEAKAGE.

⑥ **OPEN YOUR MOUTH WIDE AND BLOW**
TAKE A DEEP BREATH AND BLOW FORCEFULLY (EXCEPT FOR BABIES) INTO MOUTH OR NOSE UNTIL YOU SEE CHEST RISE.

⑦ **LISTEN FOR EXHALATION**
QUICKLY REMOVE YOUR MOUTH WHEN CHEST RISES. LIFT JAW HIGHER IF VICTIM MAKES SNORING OR GURGLING SOUNDS.

⑧ **REPEAT STEPS SIX AND SEVEN 12 TO 20 TIMES PER MINUTE**
CONTINUE UNTIL VICTIM BEGINS TO BREATHE NORMALLY.

* **FOR INFANTS SEAL BOTH MOUTH AND NOSE WITH YOUR MOUTH**
BLOW WITH SMALL PUFFS OF AIR FROM YOUR CHEEKS.

PART 1

PART 2

PART 3

4.224

Figure 1-3.—Artificial respiration and cardiac massage.

11297

Sixty-cycle frequency is considered slightly more dangerous than current of a lower frequency or d-c. The difference is small however, and the same precautions apply to 60 cycle a-c and d-c circuits.

Men differ in their resistance to electric shock, and consequently a current flow that may cause only a painful shock to one man might be fatal to another. The effects of 60-cycle current flowing through the body from hand to hand or hand to foot are summarized by three brief statements as follows:

1. At about 1 milliamp (0.001 ampere) shock is perceptible.
2. At about 10 milliamps (0.010 ampere) shock is sufficient to prevent voluntary control of muscles.
3. At about 100 milliamps (0.1 ampere) shock is fatal if it lasts more than one second.

Tests made by the Bureau of Standards show the resistance of the human body may be as low as 300 ohms under unfavorable conditions such as those caused by salt water and perspiration. This indicates that it is possible for a potential difference as low as 30 volts to cause the fatal 0.1 ampere current flow. This of course would be an extremely unfavorable condition, however, there should be no doubt as to the danger involved in even low voltage circuits.

There have been several deaths in recent years from 50 volts d-c by personnel coming into contact with welding electrodes.

The following list will show the recent deaths by electrocution of Navy and Marine Corps personnel. The majority of these accidents are due to simple carelessness.

1963

Death No.	Description	Service
1.	Grasped a line conducting electricity while standing on a truck.	USMC
2.	Electrocuted while ARC welding aboard a CVA.	Navy
3.	While erecting a radio antenna, it hit a power line.	Navy
4.	Flying a model plane with copper wire, crossed a high tension power line.	Midshipman

1963 (Continued)

Death No.	Description	Service
5.	Electrician in Radio Control - he came into direct contact with a fuse line of 2000-3000 volts. Aboard an APA.	Navy
6.	While working on power line.	Navy
7.	While welding, a heavy roll knocked him backward causing hot electrode to land on chest - aboard a Destroyer.	Navy
8.	Shocked while using a 1/4" electric drill.	Navy
9.	Sailboat struck power-line.	USMC
10.	Sailboat struck power-line.	USMC
11.	Aboard a Destroyer working on transmitter in fireroom, came in contact with a live wire.	Navy

1964

1.	Attempted to check rpm of pump with portable strobotac aboard a CVS.	Navy
2.	While working on an electrical switchboard aboard a submarine, his right leg came in contact with live power.	Navy
3.	While attempting to remove a transformer, a neutral wire snapped, throwing man into hot wire.	USMC

11298

Figure 17-11. —Sweep resolver.

Figure 17-12. —Resolver outputs.

left or right. Thus, the outputs of the stators are:

Stator 1 (to horizontal deflection coils) $= E_{in} \times \sin \theta$

Stator 2 (to vertical deflection coils) $= E_{in} \times \cos \theta$

where θ is the antenna position.

Figure 17-12 is an illustration of the outputs from the two stator windings with the antenna rotating back and forth in azimuth between the limits indicated. It should be noted that the outputs vary at a sine wave rate 90° out of phase.

TYPES OF SCANS

The discussion of the various types of CRT's thus far has been limited to construction and operating principles. However, before the CRT can be of value in airborne radar equipment, it must be capable of presenting data to the operator.

The pattern that is produced by the scanning of the electron beam over the face of the CRT determines the type of scan or presentation. The basic terms to be used are defined below.

A sweep is the trace produced on the screen of the CRT by the linear deflection of the electron beam. The movement of the sweep across or around the screen of a CRT is called scanning. This movement may also be synchronized with the movement of the antenna which is also said to be scanning a certain area of space.

There are several types of scans employed. They are usually designated by letter. The four basic types are A-scan, B-scan, C-scan, and PPI-scan. Each is discussed in the following paragraphs. The type or types of scans employed by a radar set are determined by the function the radar performs.

Although a discussion of basic types of scans may seem too basic when considering modern radar indicators, it should be remembered that most indicators can be analyzed by their basic functions and scans.

A-SCAN

Of all the types of CRT presentations, the most common is the A-scan presentation. Its main use in present-day electronics is in test and monitoring equipments. It is generally used as a test scope in the more complex radar systems. Most test equipments employing a CRT use the A-scan presentation. One of the main reasons A-scan is so common is the fact that it is a simple and relatively trouble-free system.

1127

1964 (Continued)

Death No.	Description	Service
4.	While getting more working material on a roof, man got between two high voltage wires.	USMC
5.	While lifting a radio antenna on a truck, it came in contact with a 4160-volt hot line.	Navy
6.	Repairing electrical work aboard a Minesweeper.	Navy
7.	While replacing an old oil pressure switch with a new one in #7 AC Plant aboard a Cruiser.	Navy
8.	Electrocuted when he opened the door cover of a 440 volt power panel on a pier to shield himself from heavy rainfall.	Navy
9.	While putting up a television antenna it struck a high voltage line.	Navy

1965

Death No.	Description	Service
1.	While working on a transmitter, he came in contact with a circuit breaker.	Navy
2.	When he attempted to move an oxygen test stand (Diluter Demand Regulator Flowmeter) a 440-volt power cable pulled out, causing a short circuit.	Navy
3.	While repairing a cable on a Radar Circuit panel aboard a CVS.	Navy

1965 (Continued)

Death No.	Description	Service
4.	Found in hotel with electric wire wrapped around both upper arms with the other end plugged in a wall receptacle.	Navy
5.	On leave, rendering aid to a person trapped in car, backed into another car on which some power lines had fallen.	Navy
6.	Received shock while plugging an electric drill into a socket near the engine room aboard a DE.	Navy
7.	Discovered lying on a high voltage transformer outside Commissary Store, NAF.	USMC
8.	He accidentally came in contact with high voltage wire while changing clothing after swimming.	USMC
9.	Reached up to grab a Conex box and at the same time the hoist cables of mobile crane hit tension wire.	USMC
10.	Fall due to Electrical shock.	Navy

1966

Death No.	Description	Service
1.	While using an electric drill in the Ordnance Supply Storeroom aboard a Destroyer Tender.	Navy
2.	While installing radio antenna, he came in contact with a high tension wire on a field problem.	USMC

11300

11299

1966 (Continued)

Death No.	Description	Service
3.	Car struck a utility pole, high voltage wire was knocked down.	Navy
4.	Car accident, he later was found lying next to a high tension wire.	Navy
5.	Grabbed for the extension cords that were used to light a yard that had just been watered.	Navy
6.	Was assisting in a detail moving a flag pole, the pole struck a power wire.	USMC
7.	Struck by lightning during thunder storm.	USMC
8.	Struck by lightning during thunder storm.	USMC
9.	Struck by lightning during thunder storm.	USMC
10.	Found with power lines wrapped around both legs.	Navy

1966 (Continued)

Death No.	Description	Service
11.	At Naval Air Station removing a shortwave radio antenna, it came in contact with high voltage wire.	Navy
12.	While cutting wire on light pole.	USMC
13.	Aboard a Destroyer performing maintenance in the Ship's Store and found dead.	Navy

Promoting safety within the E-division, or on the ship in general, will require that you become safety conscious. Through the use of safety reminders and by your personal example you will pass this safety conciousness on to others. Posters of the type shown in figure 1-4 are helpful as safety reminders. These posters should be changed or rotated regularly to different working areas so as to draw attention to them. Electrical safety posters are listed as NavShips 250-660-47 to 57, and they are available through the supply system for all ships and stations.

You should have regular discussions on safety within your division. Practice the procedures of applying cardiac massage and artificial respiration. Ask the ship's doctor or senior hospital corpsman to observe and/or demonstrate these procedures to your division. By knowing what to do and doing it quickly and correctly you may save a shipmate's life, or he may save yours.

11301

CHAPTER 2

THE 3-M SYSTEM

The Navy Maintenance and Material Management (3-M) System has been implemented in the Navy as an answer to the ever-present problem of maintaining a high degree of material readiness. Although the (3-M) System is designed to improve the degree of readiness, its effectiveness and reliability are dependent upon you, the individual. The accuracy with which you perform your work, along with the neat and complete recording of required data on the prescribed forms, is one of the keys to the degree of readiness of your ship and therefore is a reflection of your success as a petty officer.

The two basic elements of the 3-M System are the Planned Maintenance System (PMS) and the Maintenance Data Collection System (MDCS). The Planned Maintenance System provides a uniform system of planned preventive maintenance. The Maintenance Data Collection System provides a means of collecting necessary maintenance and supply data, in a form suitable for rapid machine processing. A Man-hour Accounting System is used aboard repair ships and tenders in conjunction with the Maintenance Data Collection System.

Preventive maintenance should not be confused with corrective maintenance. Preventive maintenance is a scheduled check on select parts of a piece of equipment. Corrective maintenance is the repair of equipment.

As a third or second class electrician, you will be concerned with both the Planned Maintenance System (PMS) and certain portions of the Maintenance Data Collection System (MDCS) as discussed in this chapter.

THE PLANNED MAINTENANCE SYSTEM

Planned maintenance reduces casualties and saves the cost of major repairs. The PMS is designed to define the minimum planned maintenance required, to schedule and control performance, to describe the methods and tools to be used, and to aid in the prevention and detection of impending casualties.

In establishing minimum planned maintenance requirements for each piece of equipment, the NavShips Technical Manual, manufacturers' technical manuals, and applicable drawings are critically reviewed. If the planned maintenance requirements are found to be unrealistic or unclear, they are modified or completely revised before being incorporated into the PMS.

It is possible that the planned maintenance prescribed in the PMS may conflict with that prescribed in other documents such as the NavShips Technical Manual. Should this happen, it must be remembered that the PMS supersedes and takes precedence over existing requirements set forth in various technical publications insofar as preventive maintenance is concerned.

THE PLANNED MAINTENANCE SYSTEM MANUAL

A master Planned Maintenance System Manual is tailored to each department of a specific ship. It contains the minimum planned maintenance requirements for each maintainable component installed in that particular department. The department Master Manuals are normally kept in the department offices and are primarily used by the department heads in planning and scheduling the maintenance requirements in their departments.

The departmental Master Manual contains a section for each division or maintenance group within the department. Each divisional section contains a table of contents and a Maintenance Index Page (MIP) for each system, subsystem, or component involved.

Applicable portions of the PMS Manual (referred to as Space Manuals) are kept in the working space for the equipment involved and

11302

serve as a ready reference to the planned maintenance required. Each MIP contains a brief description of the maintenance requirements and the frequency with which maintenance is to be effected. The frequency code is: D—daily, W—weekly, M—monthly, Q—quarterly, S—semiannually, A—annually, C—overhaul cycle, and R—situation requirement. The frequency codes for the daily, weekly, monthly, quarterly, semiannual, and annual planned maintenance actions are self-explanatory. Certain planned maintenance actions are performed once each operational cycle between shipyard overhauls, during a specified quarter of the cycle, and are designated by the code C. The code R is used to identify those planned maintenance actions which are to be performed prior to getting underway, after a specified number of hours of operation, or to meet other requirements that only arise during a specific situation (prior to overhaul, for example).

Figure 2-1 shows a Maintenance Index Page (MIP) taken from a typical PMS Manual. Information to be found on the MIP includes the system or component involved, a short description of each maintenance requirement, the maintenance frequency code plus a consecutive number starting with "1" for each frequency code assigned, the rate or rates recommended to perform the maintenance, the average time required to perform the maintenance, and related maintenance requirements. The related maintenance listed is additional planned maintenance which can be completed prior to, in conjunction with, or immediately after the scheduled maintenance.

Because shipboard application of the PMS will vary slightly from one ship to another, the information found on the MIPs regarding rates recommended to perform the maintenance and the average time required for the task requires certain clarification. The maintenance tasks are actually performed by personnel available and capable, regardless of what rate is listed on the MIP. The average time required, as listed on the MIP, does not take into account the time required to assemble the necessary tools and materials nor the time required to clean the area and put away the tools at the end of the task.

SCHEDULING OF PLANNED MAINTENANCE

For each division or maintenance group, a cycle schedule which provides a visual display of the planned maintenance requirements (based on the operational cycle of the ship between shipyard overhauls) is displayed in the departmental offices. The information to be found on the cycle schedule (fig. 2-2), for any particular division or maintenance group includes the MIP number from the PMS Manual, a listing of all the equipment within that particular group for which planned maintenance is required, and the specific quarter in which the semiannual, annual, and overhaul cycle planned maintenance actions are to be performed. The cycle schedule also lists the quarterly and the situation requirement planned maintenance actions which must be scheduled, as well as the monthly planned maintenance requirements.

The cycle schedule is used by the department head, in conjunction with his division officers and leading petty officers, to make out the quarterly planned maintenance schedule. The quarterly schedule (fig. 2-3) displayed adjacent to the cycle schedule in a holder known as the maintenance control board, gives a visual display of the ship's deployment schedule and the planned maintenance to be performed during that particular quarter.

The quarterly schedule has thirteen columns, one for each week in the quarter, for the scheduling of maintenance throughout the 3-month period.

At the end of each week, the leading petty officer of the division or maintenance group will update the quarterly schedule by crossing out (with an X) the preventive maintenance performed. If a planned maintenance action is not completed during the week it is scheduled, the leading petty officer will circle the action on the quarterly schedule. The uncompleted maintenance is then rescheduled (as shown in figure 2-3) for another week within the same quarter, normally as soon as the operating schedule of the ship will allow.

At the close of each quarter, the quarterly schedule is removed from its holder and retained on board as a record of the planned maintenance completed. This record may be discarded at the beginning of the second quarter after the next shipyard overhaul.

The quarterly schedule is also used by your leading petty officer to make out a weekly planned maintenance schedule which is posted in the space where you work. The weekly schedule of planned maintenance should not be considered as the total work for the week. This schedule only covers the scheduled planned

11305

maintenance and is in addition to the other routine work, upkeep, and corrective maintenance to be done.

The weekly schedule provides a list of the components in the working area, the appropriate page number of the PMS Manual, and spaces for the leading petty officer to use in the assignment of planned maintenance tasks to specified personnel. The daily and weekly planned maintenance actions are preprinted on the forms and the other maintenance actions are written in by the leading petty officer as required. When the leading petty officer is assured that a maintenance task has been completed, he crosses out the maintenance requirement number on the weekly schedule. If for some reason a task cannot be completed on the day scheduled, the leading petty officer will circle the maintenance requirement number and reschedule it for another day. The status of scheduled maintenance is readily available by looking at the weekly schedule.

A sample weekly schedule is shown in figure 2-4. In addition to the weekly maintenance actions, the leading petty officer has assigned Brady the responsibility of requirement M-1 on Monday and Dwyer the responsibility of S-1 on Wednesday (see fig. 2-4). In the far right-hand column, it is noted that maintenance requirements A-1 and S-1 are due within the next 4 weeks. In the schedule shown in figure 2-4, all maintenance scheduled for Monday was completed, but Brady was unable to complete the scheduled requirement A-1 for Tuesday and the action is rescheduled for Thursday of the same week.

Figure 2-4.—Weekly Preventive Maintenance Schedule.

11306

11302

THE MAINTENANCE REQUIREMENT CARD

The Maintenance Requirement Card (MRC), 5 by 8 inches, has the planned maintenance task defined in sufficient detail to enable assigned personnel to perform the task (see fig. 2-5). A master set of MRCs is maintained in the log room and those applicable to the equipment with which you are concerned are maintained in your working space. If a card in the working space becomes lost or mutilated, a new card can be made from the master set and used until a feedback report is sent in and a new card obtained.

The MRC is one of the primary tools of the PMS with which you will be concerned. Suppose that on a Monday morning Dwyer looks at the weekly schedule (fig. 2-4) and finds that he is assigned the maintenance action identified as W-1. The weekly schedule indicated that this particular maintenance action is listed on page EL-7 of the PMS Manual. The MRC which describes the task assigned is identified by the number combination "EL-7 W-1" in the upper right-hand corner. In preparation for performing the assigned task, Dwyer would pull MRC number EL-7 W-1 (fig. 2-5) from the set of cards in the working space.

The MRC identifies the component involved; gives a brief description of the maintenance requirement; lists the safety precautions to be followed; and lists the tools, parts, and materials needed to accomplish the task. This information is listed to enable you to be completely ready to perform the prescribed maintenance prior to actually working on the equipment involved. The procedure listed on the MRC is standardized and is the best known method of performing that particular task. Any related maintenance requirement listed on the MRC should be done at the same time or in conjunction with the assigned task for the purpose of time conservation.

The 16-digit number on the lower right-hand side of the MRC is the bureau card control number which can also be found on the MIP. Each MRC has a bureau card control number, which must be referred to in any correspondence concerning the card.

On some ships, two or more divisions may have identical equipment. When this occurs, each division will have separate (but identical) MRC cards for the equipment.

FEEDBACK REPORT

The PMS Feedback Report, OPNAV Form 4700-7 (fig. 2-6), is designed to report any discrepancies or suggested improvements in the PMS as installed aboard ship. The report is to be filled out by the man who discovers the discrepancy or suggests an improvement, signed by anyone designated by the commanding officer, and mailed via the type commander to the appropriate field office listed on the reverse side of the originator's copy of the form. Atlantic Fleet ships use the Norfolk address and Pacific Fleet ships use the San Diego address.

When submitting a feedback report, be sure it is filled out completely and legibly. Handwritten copies are acceptable but a ballpoint pen must be used to ensure that all copies are legible. Instructions for filling out the feedback report are listed on the back of the form and are discussed here for the purpose of clarification.

You are required to complete the "TO" line with the appropriate (San Diego or Norfolk) address. In the "FROM" line insert the hull number of your ship (DDG 11, DD789, AD 36, etc.); and in the "VIA" line indicate the type commander. The date will be the day you discover the discrepancy or suggest an improvement. The serial number indicates the number of feedback reports sent in by your ship. If your ship has previously forwarded five feedback reports, the next report will be numbered 6.

The blocks concerning the system, subsystem, component, M.R. number, and the bureau card control number should be filled in with information from the appropriate MIP and/or MRC. If the MRC or MIP is missing and the bureau card control number is not available, the equipment should be identified by its name and its APL/CID or AN number. The APL/CID number identifies the parts list for the equipment and is found in the index to the Coordinated Shipboard Allowance List (COSAL). The "Technical Publication" block in the "Discrepancy" section of the report is intended to include all Naval Ship Systems and Naval Ordnance Systems Command publications. In the event that any of these are in error, identify the publication number, volume, revision, date, change number, page paragraph, and/or figure.

11308
11307

SYSTEM	COMPONENT	M. R. NUMBER
Electric Plant	Ship Service Generator	EL-7 W-1
	MAINT. SIGNI-FICANT NO.	
SUB-SYSTEM	RELATED M.R.	RATES / M.H
Electric Power Generation	None	EM3 / 1.0

M. R. DESCRIPTION

1. Clean the generator.
2. Measure the insulation resistance of the generator and excitation circuit.

TOTAL M/H 1.0
ELAPSED TIME: 1.0

SAFETY PRECAUTIONS

1. Observe standard safety precautions.
2. Wire air starting/steam inlet valve shut and tag "Do Not Open." On electric start system, disconnect starting motor at battery terminals and tag "Out Of Service."

TOOLS, PARTS, MATERIALS, TEST EQUIPMENT

1. 500-volt Megger
2. AN-PSM-4 Multimeter
3. 8" Screwdriver
4. 8" Adjustable wrench
5. Wire, 24 gauge
6. Safety tags
7. 6" Slip-joint pliers
8. Voltage tester
9. Lint-free rags
10. Vacuum cleaner

PROCEDURE

NOTE 1: Measure the insulation resistance weekly, when securing the generator and before starting, if it has been idle for one week or more.

Preliminary

a. Wire air starting/steam inlet valve shut and tag "Do Not Open." On electric start system, disconnect starting motor at battery terminals and tag "Out Of Service."
b. Open generator circuit breaker and tag "Out Of Service." Test with voltage tester to determine generator side of circuit breaker.
c. Open disconnect links where installed and tag "Out Of Service."

1. Clean the Generator.
   a. Remove inspection covers.

(Cont'd on Page 2)

Page 1 of 2 | EA | ZZZG | GG1 | 45 | 8624

LOCATION | W

A

Procedure (Cont'd)

b. Vacuum all interior surfaces and components that can be reached without disassembly of the generator, and wipe with dry rags.

2. Measure the Insulation Resistance of the Generator and Excitation Circuit.

NOTE 2: Measure the stator insulation resistance at the generator side of the generator circuit breaker.

a. Measure the insulation resistance of the stator using 500-volt megger.
b. Lift the brushes. Measure the insulation resistance of the field from a slip-ring to ground, using 500-volt megger.

CAUTION: Do not megger the excitation circuit.

c. Measure the insulation resistance of the excitation circuit from a brush holder to ground, using the multimeter.

NOTE 3: If insulation resistance is less than 0.5 megohm, take corrective action.

CAUTION: Do not snap springs in place, as this may crack or chip the brushes.

d. Lower the brushes and reinstall cover.
e. Remove wire and tags. Reconnect starting motor, as applicable.
f. Set up for prescribed operation.

Figure 2-5.—Maintenance Requirement Card (MRC). (A) Front Side, (B) Reverse Side.

11308

The display of information in an A-scan system is presented in both the horizontal and vertical planes. Range or time is usually displayed on the horizontal and signal intensity or amplitude on the vertical. The type of CRT used is most often the electrostatic type rather than the electromagnetic, because the electrostatic is the least complex in its design. Range measurement on an A-scan presentation is illustrated in figure 17-13.

Range is measured on the horizontal sweep from left to right. The first pulse seen on the extreme left is the transmitter firing. The second pulse is a negetive pulse used as a range mark and indicates a total time of 12.36 microseconds or 1 radar range mile. The next negative pulse would be the 2-mile marker, etc. The next pulse, a positive pulse, would be a target return at approximately 2 1/2 miles. Following this, you see a positive and a negative pulse coincident in time at 3 miles. The positive pulse is a target return; the negative pulse would be a 3-mile marker. The next pulses are negative 4- and 5-mile markers, respectively. The negative pulses could be replaced by positive pulses or by bright or dark spots (intensity modulation). Another method of obtaining markers is to etch the scope face with lines indicating certain ranges. The disadvantage of the last system is that it will not compensate for nonlinearity in the trace nor will it be a flexible system. Range changes would be almost impossible.

Comparing the A-scan to other types, the A-scan system gives very accurate ranging, gives good definition of relative target sizes, is simple and inexpensive, and is relatively trouble free. On the other hand, it will not give an easily interpreted geographical presentation nor does it give azimuth information.

Figure 17-14 is the simplified block diagram of a typical A-scope system, which is presented to establish a basic understanding of scopes before discussing the more advanced types.

Sweep Circuit Theory

The frequency of the output waveform from V1 (fig. 17-15), a single-swing blocking oscillator, is governed by the RC time of R1, R2, and C1. Since R2 is the only variable component, it is the frequency adjustment. The output of the circuit is a positive pulse developed across R3 when V1 conducts.

This positive pulse is coupled through C2 to the input of V2, a cathode follower. The input of the cathode follower is developed across its grid resistor, R4, and applied to the control grid. This causes a pulse of current through the tube, which develops a signal across R5 and R6, giving an output signal similar to the

Figure 17-13. —A-scan presentation.

OPNAV Form 4700/7 (10-65)

40.101

Figure 2-6.—Feedback Report (OPNAV 4700-7).

Prior to the distribution of the report (as indicated on the original and each of the four carbon copies), check it for completeness. The discrepancy should always be explained clearly and a suggestion for its correction must always be offered.

THE MAINTENANCE DATA COLLECTION SYSTEM

The Maintenance Data Collection System is designed to provide a means of recording maintenance actions in substantial detail so that

11309

a great variety of information may be collected concerning maintenance actions and the performance of equipment involved. In addition, the system provides data concerning the initial discovery of a malfunction, how the equipment malfunctioned, how many man-hours were expended, which equipment was involved, what repair parts and materials were used, what delays were incurred, the reasons for delay, and the technical specialty or work center which performed the maintenance.

Codes must be used in recording maintenance actions in order to allow converting the information to a language that can be read by automatic data processing machines. As a third or second class electrician, you will be required to fill out various maintenance forms, using the codes listed in the Equipment Identification Code (EIC) Manual. The forms are sent to a data processing center where the coded information is punched into cards which are machine processed to produce the various reports for use in maintenance and material management.

The reports that are produced by the automatic data processing machines will be accurate and useful only if the information is clearly and accurately entered on the maintenance forms. Therefore it is very important that the codes which you enter on the forms be accurate and clearly written.

MAINTENANCE DATA COLLECTION SYSTEM FORMS

The MDCS forms on which you may be required to make coded entries include OPNAV Form 4700-2B (Shipboard Maintenance Action), OPNAV Form 4700-2C (Work Request), and OPNAV Form 4700-2D (Deferred Action). Detailed descriptions of the entries to be made on these forms are listed in the EIC Manual and in chapter 3 of the 3-M Manual (OPNAV 43P2). Brief descriptions of these entries are also listed here to help you become familiar with the forms, which are shown in figures 2-7 through 2-10.

Block A, Ship Name and Hull No./Activity: Enter the name and hull number of your ship—for example, USS Now (DD 746).

Block 1, Administrative Organization: Enter the 4-letter/number code (from section II of the EIC Manual) to which your ship is assigned (if your ship is assigned to DESRON 7, you would enter DO70).

Block 2, Unit Identification Code (UIC): Enter the UIC number for the ship or activity for which the maintenance was performed. This entry is obtained from NavCompt Manual, Volume 2, Chapter 5.

Block 3, Maintenance Control Number: This number is used to relate all documents submitted on a specific job and is filled in by the maintenance control section of your ship before the documents leave the ship. The numbers will be assigned consecutively beginning with 0001 and ending at 9999. Upon reaching 9999, the series will be started again at 0001.

Block 4, Date: Enter the day, month, and year the maintenance is accomplished; or, for a work request, enter the date the request is submitted.

Block B, Type Availability: This block is left blank on all forms except the Work Request, OPNAV Form 4700-2C. On the work request, this block will be filled in with a single-letter code, taken from section IX of the EIC Manual, to identify the type of availability in which the repair activity will perform the maintenance.

Block 5, Equipment Identification Code: Enter, from section X of the EIC Manual, the appropriate 7-letter/number code which identifies the system, subsystem, component, and/or lowest designated assembly on which maintenance is requested or performed. Caution must be exercised to ensure that the EIC number correctly identifies the exact item on which maintenance is requested or performed.

Block 6, Work Center: Enter the 3-letter/number code from section III of the EIC Manual which identifies the department, rating, shop, or group which performs the maintenance actions on the equipment identified in the equipment identification code, block 5.

Block 7, Assisting Work Center: Leave blank. When information is required in this block it will be filled out by your supervisor in accordance with the EIC Manual and chapter 3 of the 3-M Manual.

Block 8, Repair Activity Unit Identification Code (UIC) obtained from NavCompt Manual, Volume 2, Chapter 5.

Block 9, How Mal/MRC: If the action is a result of a malfunction, list the 3-digit code from section IV of the EIC Manual which best describes the trouble. If the action is planned maintenance (MRC), enter a 3-letter/number combination code which identifies the frequency check on the equipment. For example, if the situation is an M-1 PMS action enter MO1.

17.81B

Figure 2-7.—Shipboard Maintenance Action Form (OPNAV 4700-2B).

For all other actions three zeroes (000) will be entered.

Block 10, Discovered: Enter the appropriate code from section V of the EIC Manual which identifies when the maintenance requirement was discovered.

Block 11, Action Taken: Enter the code from section VI of the EIC Manual which best describes the maintenance action taken. "Not Repairable This Ship" (NRTS) codes will be used only by repair activities.

Block 12, Units: Enter the number of identical items, identified in block 5, on which the same maintenance action was attempted, performed, or requested. If identical alterations or significant maintenance actions are accomplished on identical equipment bearing different serial numbers, each equipment will be reported on a separate document.

Block 13, Man-hours: On completion of the maintenance action, enter the total man-hours (to the nearest tenth) expended by all shipboard personnel. If the task was completed in 1-1/2 hours, for example, you would enter "0015". Enter a "0" in any space not used.

Block E, Blank: Leave blank, (explained later).

Block 14, Serial Number: For detailed information on completing this particular block, see chapter 3 of the 3-M Manual. For mechanical/electrical equipment, the serial number is not required; instead, the shipboard numbering identification system will be used, followed by the abbreviated name of the equipment. For example, if block 5 identified a main feed pump, and the pump in question is number 1, block 14 should contain the entry "NR 1 MNFDPMP."

that have been performed at the shipboard level by shipboard personnel. All planned maintenance actions except daily and weekly planned maintenance actions must be recorded on this form in addition to checking them off on the weekly and quarterly schedules. Routine preservation such as chipping, painting, and cleaning should not be reported.

The weekly schedule shown in figure 2-4 reflects that Brady completed maintenance requirement EL-4 M-1 on Monday. Figure 2-7 shows the Shipboard Maintenance Action form which Brady completed for this maintenance requirement. Note that, in addition to giving the date (16 Aug. 1966), the man-hours (8.5), and the proper codes taken from the EIC Manual, Brady has given a brief description of the maintenance performed (in block F) and has signed the form. His leading petty officer has signed the form to indicate the information is complete and accurate.

Any corrective maintenance actions that are deferred because of the ship's operations, lack of repair parts, or the requirement of outside assistance are reported on the Deferred Action Form (fig. 2-8) (OPNAV 4700-2D). The first sheet of this 2-sheet document is used to record and report the reason for deferral and the second sheet is used to report the completion of the maintenance action. If a corrective maintenance action must be deferred, this form is required at the time a malfunction is noted. A sample sheet 1 of the Deferred Action Form which could have resulted is shown in figure 2-8. The action taken code, block 11, and the man-hours expended, block 13, on sheet 1 of the Deferred Action Form apply only to the action taken man-hours involved at the time of the discovery of the malfunction.

Figure 2-9 shows a Work Request (OPNAV Form 4700-2C) to have the motor stator

F. DESCRIPTION/REMARKS

Vent set 1-64-2 failed during operation. Investigation indicated stator windings burned out due to over lubrication. Winding insulation was grease-encrusted. No rewinding facilities on board. Rewound by USS FRONTIER, AD-25, tested and returned onboard, Installed onboard 29/8/66.
Operation is satisfactory.

FOR LOCAL USE ONLY

L. SIG. (3) B. Brady Em 3
M. SIG. (4) L. Crider Em 1

17.81D

Figure 2-10.—Deferred Action Form, Sheet 2.

rewound. In completing block F (Description/Remarks) of the work request, note that:

1. The component must be identified by name.
2. The CID number of the component must be listed.
3. The alterations number must be given, if applicable. If not applicable, it must be listed as N/A.
4. A description of what is wrong with the equipment and what you desire the repair activity to do must be given.

The signature blocks G, H, and J are to be signed by three leading petty officers, one from each duty section, who are familiar with the work to be done by the repair activity. Signature block K will be used by the commanding officer or his authorized representative to indicate command approval of the request for repair assistance.

After the repairs have been completed by the repair activity, "sheet 2" of the Deferred Action Form (fig. 2-10) is completed by entering the date of completion in block 4, the action taken code in block 11, the additional man-hours in block 13, and appropriate remarks in block F. The form is then signed by the man doing the work and by his supervisor, and is then submitted to the data processing center.

The information contained in blocks A, 1 and 2 of OPNAV Forms 4700-2B, 4700-2C, and 4700-2D will be identical on all forms for any particular ship; if desired, this information may be preprinted by the ship. Each maintenance action is assigned its own unique maintenance control number; if a maintenance task requires more than one form, as in the example using figures 2-8 through 2-10, the numbers will be identical.

Personnel attached to repair activities are required to record certain information on a

1134

Work Supplement Cards (not shown) for each repair job. Work supplement cards will be explained to you by your division petty officer if you are assigned to a repair activity.

MATERIAL USAGE AND COST DATA

The documentation of material usage and cost data on maintenance transactions requires the joint effort of the supply and maintenance personnel on board your ship. Economy of effort and the elimination of duplicate recordings are highly desirable.

Any time that repair parts or materials are drawn from the supply department for shipboard maintenance, a NAVSANDA Form 1250 is used to request the materials from supply. Maintenance personnel are required to furnish the work center code and the EIC taken from the EIC Manual, the component identification (CID) number, the maintenance control number, the name of the part, quantity required, and the stock number when submitting this form to the supply department. The supply personnel will then complete the form; the cost is documented from this form if the ship does not have data processing equipment aboard. If the ship has data processing equipment, a DD Form 1348 is used instead of the form 1250.

When the material to support a maintenance action is obtained from outside the normal supply channels or from pre-expended material bins, the reverse side of the appropriate OPNAV Form (OPNAV 4700-2B, 4700-2C, or 4700-2D) is used. The reverse sides of OPNAV 4700 series forms are essentially the same. The reverse side of OPNAV Form 4700-2C is shown in figure 2-11. On this side of the form, when appropriate, you will enter the CID number, the source code taken from section VIII of the EIC Manual, the cognizance symbol taken from supply publications to identify the supply account and the inventory manager of the item used,

CID/APL/AN 55376101

SOURCE CODE	COG.	FEDERAL STOCK NO./PART NO.	REFERENCE SYMBOL/NOVN	MATERIAL REQ. UNITS	MATERIAL REQ. QUANTITY	MATERIAL USED UNITS	MATERIAL USED QUANTITY	UNIT PRICE

11315

the Federal Stock Number, the reference symbol taken from circuit diagrams or the name of the part being replaced, the unit of issue of the material used, quantity used, and the unit cost (except on pre-extended material) of the item.

THE MAN-HOUR ACCOUNTING SYSTEM

The Man-hour Accounting System, sometimes referred to as Exception Time Accounting (ETA), is designed and intended for use by repair activities in conjunction with Maintenance Data Collection System. It is basically a management tool and accounts for deviation from a normal working day.

As a third or second class petty officer assigned to a repair activity, your only concern with this system will be when you are absent from your assigned working space for more than 20 minutes at a time. If this occurs, your leading petty officer will hand you a Daily Exception Card on which you will be required to fill in the date of change and the number of hours concerned to the nearest tenth of an hour, and then return the card to your supervisor.

In the example card shown (fig. 2-12), Jones, K.P. EM 3 (004 code) assigned to the electrical repair shop (51A code) for direct labor (01 code) was absent for one and a half hours. This absence was to take care of personal affairs and is therefore a non-duty absence as shown by the reverse side of figure 2-12.

CHAPTER 3

ELECTRICAL CABLES AND ACCESSORIES

Proper cable installation and maintenance are as important to the continued operation of an electrical system as the proper installation and maintenance of the equipment to which the cable is connected. The Electrician's Mate must have a thorough knowledge of the various types, sizes, capacities, and uses of shipboard electrical cable, and be capable of selecting, installing, and maintaining cable in such a manner as to ensure its adequacy. The repair of battle damage, accomplishment of ship alterations, and some electrical repairs may require that changes or additions to the ship's cable installation be made by the Electrician's Mate. During shipyard and tender availabilities, he may be required to inspect, test, and approve new cable installations.

The EM should avail himself of the Cable Comparison Guide, NavShips 250-660-23, which is available by submission of a Request for Issue or Turn-in (DD Form 1150) to the ship's supply department. The supply department then initiates procurement on DD Form 1348 or DD Form 1348m, whichever is appropriate. This guide fills a need for information on the use of electric shipboard cable, particularly for the selection of substitute cable items for replacement of obsolete items. Cable items are listed in the guide by general classifications as to construction and service conditions. These broad groupings are broken down into types and sizes, and indicated as being current (C), discontinued (D), or obsolete (O), as shown in column 1 of Table 3-1. Discontinued types and sizes have been eliminated from production in order to conserve certain materials, to simplify procurement, to reduce cost, to save weight and space and to secure better performance. Existing stocks should be used until depleted. Obsolete types have been superseded by current and discontinued (yet available in stock) items which are superior for Navy shipboard use. Chapter 9005 of the NavShips Technical Manual includes replacement cable lists.

The term "watertight cable," designated by an asterisk (*) in the cable guide and in Table 3-1, indicates standard cables in which all spaces under the impervious sheath are filled with material to eliminate voids and to prevent the flow of water through the cable by hose action in the event that an open end of cable is exposed to water under pressure.

An observation which the EM will make is the absence of gage numbers for specifying wire sizes of shipboard cables. This absence is partly due to naval usage of conductors that have other values of cross-sectional area (circular mils) than commercial sizes made to gage-valued specifications. In 1911 the United States Navy adopted the MIL (.001 of an inch) and the related CIRCULAR MIL to specify wire sizes for shipboard cable installations. These units are defined in Basic Electricity, NavPers 10086-A.

The adequacy of an electrical cable installation is not only concerned with current-carrying capacity and insulation strength, but because of the varied service conditions aboard ship, is also related to the ability to withstand heat, cold, dampness, dryness, bending, crushing, vibration, twisting, and shock. No one type of cable has been designed to meet all of these requirements; therefore, a variety of types are employed in a shipboard cable installation.

Cable types are grouped under four (4) general classifications as follow:

1. Cables for nonflexing service
2. Cables for repeated flexing service
3. Cables for special purposes
4. Miscellaneous cables

Reels, coils, and containers of cable shipped by manufacturers are marked to show the year of manufacture. Markings will consist of a strip approximately two inches wide and colored

11318

Figure 17-14.—Block diagram of an A-scope system.

input. C4 is a decoupling capacitor used to prevent signals from appearing in the B+ line. The cathodefollower output triggers the single-kick multivibartor (V3 and V4) through C3.

V3 is biased to cutoff, in the static state, due to the zero bias conduction of V4 through R9. The positive input pulse to V3 overcomes this bias, causing V3 to conduct. A negative signal is then coupled to the grid of V4 by C5. This cuts off V4 which will remain cut off until C5 has discharged through R9, R10, and R11. When C5 has discharged, both tubes will return to the static state condition. This completes one cycle of operation.

While V4 has cuttoff, a positive unblanking pulse was coupled to the scope through C7. During the time V3 is conducting, a negative pulse is coupled to the grid of V5 by C6. V5 is a sweep generator and will remain cut off as long as V3 conducts. During this cutoff period, a sawtooth voltage will be developed across C8. The sweep time is determined by the RC time of R14, R15, and C8. The sawtooth sweep voltage is coupled to the sweepamplifier through C9.

B-SCAN

Often the situation in which a radar is used calls for simplicity of circuitry and construction; therefore, B-scan is often used.

In B-scan, three variables are possible. These are range, a function of time; azimuth, a function of antenna rotation; and the intelligence received by the radar or associated equipment.

From the operator's standpoint, the ideal situation would be the presentation of an exact replica of the area scanned. This would involve complicated construction and circuitry. The B-scan represents a compromise between the extremes of simple and complex circuitry.

B-scan involves the simplest circuitry and construction of any two-dimensional presentation and yet presents information in a reasonably faithful replica of the area scanned by the

1964	blue
1965	white
1966	red
1967	green
1968	orange

CABLE DESIGNATIONS

Shipboard electrical cables are identified according to type and size. The type designations consist of letters that indicate construction or use. The letters in column 2 of table 3-1 are typical.

TYPE AND SIZE DESIGNATIONS

The types and sizes of lighting and power cables for shipboard applications are numerous. The initial letter of the type designation for lighting and power cables indicates the number

11319

of conductors the cable contains. These initial letters are S, D, T, or F and indicate, respectively, single, double, triple, or four conductors. Also included in this lighting and power group is the 6SGA type cable (with 6 conductors) which is listed in table 3-1.

The SSGA cable designation shown on table 3-2 indicates by the initial S a single conductor, the SGA part of the designation means shipboard, general use, armored.

The SGA type cable employs silicone rubber and glass as primary insulation, making it heat and flame resistant. Figure 3-1 shows the construction of a DSGA cable. The specified number of insulated stranded copper conductors (listed in columns 2 and 3, in table 3-1) are enclosed in an impervious sheath, braided metal armour, and paint. The cable has a maximum voltage rating of 1000 volts a-c or d-c, and is made watertight by the application of waterproof sealing compound to all interstices (voids) of the conductors and cable core. They supersede the type HFA (Heat and Flame resistant—Armored) whose construction contained synthetic resin and felted asbestos insulation for the smaller sizes (size 3, 4, and 9, shown in table 3-1) and contained asbestos-varnished cambric-asbestos insulation for larger sizes. SGA cables are designed to have a minimum outside diameter and weight as compared to older type cable. In table 3-1 compare the newer type TSGA-3 with the older type THFA-3. It is apparent that both cables will carry the same amperage, but the newer type TSGA-3 is approximately 18% smaller in outside diameter and the weight per foot is 25% less than the older type THFA-3.

From this comparison it can be seen that by using the newer cable we can save on space and weight which is at a premium on combatant naval vessels.

The SGA cables also supersede the type LPA (Lighting and Power, Armored) cables. The LPA contain natural rubber insulation in the smaller cables and varnished cambric insulation in the larger sizes. They are processed (cabled) with filler and binder materials, all of which is covered with a rubber-hose jacket, then armored. SGA cables also supersede the type FPA (Flame Proof—Armored) that contain natural rubber or asbestos-varnished cambric-asbestos insulation, depending on size, cabled with fillers, felt, armored.

Let us inspect further the notations in column 2 of table 3-1. The numerals immediately following the type letters indicate the size of a single conductor, by giving the approximate cross-sectional area expressed in thousands of circular mils. For example, TSGA-3 indicates approximately 3 thousand circular mils; table 3-1 shows the actual area to be 2,828 circular mils. Type SSGA cable is available in conductor sizes ranging from 2,828 through 2,097,000 circular mils (SSGA-3 through SSGA-2000); DSGA and TSGA from 2,828 through 413,600 circular mils (DSGA-3 through DSGA-400 and TSGA-3 through TSGA-400); and FSGA from 2,828 through 60,090 circular mils (FSGA-3 through FSGA-60).

Table 3-1 lists the sizes of stuffing tubes used with particular types and sizes of cable. Metal stuffing tubes are used generally for deck and bulkhead; these tubes are specified for size as shown in the first row of table 3-3 and repeated in column 4 of table 3-3 by using letters. On the other hand, numerals from 1 through 9 are used for nylon stuffing tubes that have generally replaced metal tubes for cable entry to equipment enclosures.

The Electrician's Mate must also identify cables used for degaussing service. Here the initial letters have been restricted to S and M for identifying Single or Multiple conductors, respectively. Thus, SDGA is a Single conductor, DeGaussing, Armored cable. These letters are followed by numbers that have the same significance explained above, which give the approximate cross-sectional area expressed in thousands of circular mils.

TYPE AND SIZE EXCEPTIONS

After analyzing hundreds of symbols for designating type and size as would be given in table 3-1, one becomes aware that a uniform rule for forming them has been attempted. This is true. However, such practice is not uniformly applicable.

A consistent interpretation of the letter T means THREE, as noted in table 3-1. One example of departure is observed (fig. 3-2D) for the TTHFWA-10, where T means Twisted-pair and Telephone. Elsewhere, T sometimes means Tough-jacket as used to identify the TRXF; the next initials (RXF) mean silicone-or-synthetic-Rubber, eXtra Flexible items.

29.226

Figure 3-1.—Type DSGA shipboard nonflexing service cable.

29.226

Figure 3-2.—Nonflexing service cable for special use.

These are classified as special purpose cables, used specifically for welding and portable equipments.

Similarly, departures are noted regarding the use of numerals for "Size Designations" since the numerals may indicate one or more of the following:

1. Number of copper conductors
2. Size of copper conductor
3. Number and size of a conductor
4. Size and number of strands per conductor
5. Number of twisted pairs
6. Maximum rms rated voltage

Examples of the above are as follows:

1. Example: Type MSCA-7 is a Multiple-conductor, Shipboard, Control, Armored cable with 7 conductors. The tabulation in the cable guide would show the area in circular mils.
2. Example: Type FSGA-23 shown in table 3-1 is representative where the numerals indicate the approximate cross-sectional area of any SINGLE conductor expressed in thousands of circular mils (abbreviated in tables variously as CIRMILS or C.M. or cm). This particular item has approximately 23,000 cm (exactly 22,800 cm).
3. Example: The previously described TTHFWA-10 is applicable here. It has 10 pairs, meaning 20 conductors.
4. Example: SS5P designates Single-conductor, Shipboard, 5000 volt, Propulsion; made with silicone treated glass tape insulation, binder, impervious sheath, armored. Comparable sizes of this current (C) cable

replace some of the type SHFP (see fig. 3-2B), especially where the SHFP items have only a 3000-volt rating. Other SHFP items have the desired 5000-volt rating with procurement discontinued (D). The Electrician's Mate should check chapter 9005 of NavShips Technical Manual whenever problems of availability arise, being very certain that the latest edition is being consulted.

NONFLEXING SERVICE

Nonflexing service cable designed for use aboard ship is intended for permanent installation and is commonly referred to as such. The cables that are described in the previous paragraphs for use with lighting and power circuits are intended for this nonflexing service. This nonflexing service can be classified further according to its application and is of two types—general use and special use.

GENERAL USE

Nonflexing service cable is intended for use in nearly all portions of electric distribution systems, including the common telephone circuits and most propulsion circuits. Special cases in d-c propulsion circuits for surface ships are excepted in which the impressed voltage is less than 1000 volts.

The previously described SGA (Shipboard, General-use Armored) cable is one type generally found in this general use, nonflexing service.

In this classification is the type MSCA which is a reduced diameter (Multiple-conductor Shipboard, fire control, Armored) watertight cable for use in interior communications, as well as in fire control circuits. This MSCA supersedes the older MHFA type cable.

Cables which are used for small-boat services also are classed within this general use, nonflexing service. Representative is the current (C) series that include the DBSP, TBSP, and FBSP cables; their first initials (D & T & F) as in table 3-1 stand for the number of conductors they contain, namely, Double, Triple, and Four conductors; the initials BSP mean small-Boat, Shielded, Plain. They are constructed with synthetic insulation, cabled with fillers, copper tape shield, gray impervious sheath overall. Numerals follow these initials as in column 2 of table 3-1, which also indicate their approximate cross-sectional area expressed in thousands of circular mils. Here you also find the DBSP-3/5 cable where the fraction 3/5 means "three-fifths of one-thousand cm", or "600 cm" approximately; the tabulation in the cable guide shows the actual area is 703 cm.

SPECIAL USE

There are many shipboard electrical circuits where special requirements of voltage, current, frequency and service must be met in the cable installation and other circuits where general-use, nonflexing service cable may meet the necessary requirements, yet be economically impracticable. For these reasons, there are many different types of nonflexing service cable for specialized use, such as degaussing, telephone, radio, and casualty power. Some of these cables are shown in figure 3-2.

Type MDGA (fig. 3-2A) is a multiconductor cable used in degaussing circuits. Type PBJX (replaced by type TCJA-mil-C-2194 on new construction) cable (fig. 3-2C) consists of one conductor of constantan (red) and one conductor of iron (gray), and is used for pyrometer base leads. Type TTHFWA (fig. 3-2D) is a multiconductor, twisted-pair cable used for telephone circuits.

REPEATED FLEXING SERVICE

Repeated flexing service cable designed for use aboard ship is commonly referred to as being portable because it is principally used as leads to portable electric equipment. It is also of two types—general use and special use.

GENERAL USE

Repeated flexing service cable, which is designed for use as leads to portable equipment and permanently installed equipment where cables are subjected to repeated bending, twisting, mechanical abrasion, oil, sunlight, or where maximum resistance to moisture is required, is distinguished by the letter designation, HOF (Heat and Oil resistant, Flexible).

11325

This cable contains stranded copper conductors that are insulated with butyl rubber, covered with a tape or braid. The designated number of conductors are twisted together, held by a binder, and covered with an impervious sheath (fig. 3-3).

Repeated flexing service cable designed for general use is of four different types, depending on the number of conductors.

The types are SHOF (single conductor), DHOF (two conductor), THOF (three conductor), and FHOF (four conductor). Type SHOF cable is available in various conductor sizes ranging from 2594 (SHOF-3) through 812,700 circular mils (SHOF-800); types DHOF and THOF from 2613 (DHOF-3 and THOF-3) through 413,500 circular mils (DHOF-400 and THOF-400); and type FHOF from 2613 (FHOF-3) through 137,800 circular mils (FHOF-133).

SPECIAL USE

There are many different types of repeating flexing service cable designed for special requirements of certain installations, including type TTOP and casualty power cables. Two of these types are shown in figure 3-4. Type MHFF (replaced by MHOF-Mil-C-915B) (fig. 3-4A) is used for control circuits in revolving structures, and type TRF (fig. 3-4B) is used for arc-welding circuits.

INSTALLATION

Electrical cables installed aboard U. S. Naval vessels must meet certain requirements determined by the Naval Ships Systems Command. These requirements, published in the General Specifications for Ships of the U. S. Navy, are too numerous to cover in detail in this training course; hence, only the more basic ones are included.

The job of installing nonflexing service cable may be performed by the Electrician's Mate whenever necessary to repair damage or to accomplish authorized ship alterations. Before work is begun on a new cable installation, cableway plans should be available. If repairs to a damaged section of installed cable are to be effected, information on the original installation can be obtained from the plans of the ship's electrical system, which are normally on file in the engineering department office (log room) aboard ship. If a ship alteration is to be accomplished, applicable plans not already on board can be obtained from the naval shipyard listed on the authorization for the alteration (SHIP ALT) at the planning yard for the ship.

Cables installed aboard ship must have maximum usable life under service conditions of temperature, moisture, and mechanical abuse. Also, they must have minimum weight for the service intended. The cables must be located to (1) minimize damage from battle action, (2) avoid physical and electrical interference with other equipment and cables, and (3) provide for the maximum dissipation of internally generated heat.

SELECTING CABLE

Two-conductor cable shall be installed for 2-wire, d-c and single-phase, a-c circuits. Three-conductor cable shall be installed for 3-wire, d-c or 3-phase, a-c circuits. Four-conductor cable shall be installed where two 2-wire lighting circuits are run in the same

29.226

Figure 3-3.—Type DHOF cable.

11326

29.226

Figure 3-4.—Repeated flexing service cable for special use.

cable. Four-conductor and multiconductor cable shall be installed for control circuits and communications circuits as necessary.

Ambient temperature, load current, and voltage drop are the principal factors that determine the proper size cable to be used in a particular installation. Ratings and characteristics tables, which specify the maximum current carrying capacities of the various types of shipboard electrical cables at 40° C and 50° C ambient temperatures, are contained in Chapter 9005 of the NavShips Technical Manual. Cables installed in U. S. Naval vessels must comply with the requirements of these tables. A portion of the table for nonflexing service cables is shown in table 1.

To select the proper size cable for a particular installation, it is necessary to know (1) the total connected load current, (2) the demand factor, (3) the resultant load current, and (4) the allowable voltage drop.

The total connected load current for d-c power circuits is determined by adding the sum of the rated current of the connected loads as listed on the identification plates of connected motors and appliances and an additional 100 watts for each receptacle not specifically indicated. For a-c power circuits the connected load current of the connected motors and appliances is added vectorially to obtain the total connected load current.

The demand factor of a circuit is the ratio of the maximum load averaged for a 15-minute period to the total connected load on the cable. If the feeder demand factor for a group of loads cannot be determined, a value of 0.9 may be assumed. For power systems supplying a single-phase load or for a lighting system branch, submain, and main circuits, the demand factor is unity.

The resultant load current is the product of the total connected load current and the demand factor of the circuit. For most installations with which the Electrician's Mate is concerned, the resultant load current and the total connected load current will be the same value. In other words, the demand factor of these circuits will be unity. Cable sizes are usually selected on the basis of maximum current-carrying capacity and allowable voltage drop. However, if the length of the cable installation is short and the total connected load is small, the resultant load current is usually the principal factor that determines the size of the cable to be used, and it is not necessary to calculate the allowable voltage drop. For other cases, however, the allowable voltage drop would be determined by design engineers, either at the time the ship was planned, or during ship alterations for addition of major equipments at the planning yard for the ship.

The voltage drop (difference in voltage between any two points in a circuit) is expressed as a percentage of the rated switchboard (or switchgear group) bus voltage or the transformer nominal voltage. The maximum percent voltage drop allowed for a circuit is specified by the Bureau of Ships and varies according to the intended service of the circuit. For example, GENERAL SPECIFICATIONS FOR SHIPS specifies that the size of cables for an a-c ship's service lighting system, when calculated using a resistivity of 12 ohms per circular mil foot (resistivity of copper at 45 degrees centigrade), will not exceed 6 percent exclusive of transformer regulation.

WIREWAYS

Before installing new cable, survey the area to see if there are spare cables in existing wireways and spare stuffing tubes that can be used in the new installation. The cable run must be located so that damage from battle will be minimized, physical and electrical interference with other equipment and cables will be avoided, and maximum dissipation of internally generated heat will occur.

11327
11328

First consideration must be to protect the cable against battle damage. The protection afforded by the ship's structure must be fully used. Do not run cables on the exterior of the deckhouse or similar structures above the main deck, except where necessary because of the location of the equipment served, or because of structural interferences or avoidance of hazardous conditions or locations. Where practicable, route vital cables along the inboard side of beams or other structural members to afford maximum protection against damage by flying splinters or machine gun strafing. Where exposed runs of vital cables are unavoidable, a method of protection approved by the Bureau of Ships must be used.

Where practicable, avoid installing cable in locations subject to excessive heat, and never install cable adjacent to machinery, piping, or other hot surfaces having an exposed surface temperature greater than 150° F. In general, cables shall not be installed where they may be subjected to excessive moisture. Cable runs that are unavoidably near fire mains and water, steam, oil, or other piping should be provided with drip-proof shields or other barriers to protect against damage from leaks or high-temperature steam.

If any other location is practicable, electric cables should not be run through spaces where hazardous materials are stored or handled (hangar spaces, powder magazines, gasoline stowage compartments, etc.) or through adjacent spaces that are normally open to such spaces. If cables must be run through hazardous spaces, only heat- and flame-resistant armored cable shall be used in such spaces, and through cables shall be of unbroken length within spaces. Cables terminating at equipment in these spaces shall be of unbroken lengths; however, a single cable may be run between lighting fixtures when more than one fixture is installed in such spaces.

Cables that terminate in, or are routed solely within, highly hazardous spaces, such as gasoline pump rooms, and gasoline filter rooms, must be provided with special protection. Protect these cables by installing them in watertight or channel-shaped steel casings of sufficient strength. Air spaces must be provided between protective casings to facilitate heat dissipation and to prevent condensation of the cables. Drainage must be provided for the casings (fig. 3-5).

Cables that run through gasoline stowage compartments and spaces containing stowage for other flammable volatile liquids must be installed in an insulated trunk (fig. 3-6). They should be installed so that they are not supported on the trunk itself. Bolted access plates should be provided in each stuffing tube area where cable trunks are used.

Cables that run through tanks containing combustible liquids must be provided with concentric pipe enclosures (fig. 3-7).

Replacement of defective cables in lighting and power systems may also require replacement of cable fittings. In selecting substitute cables, careful attention should be given to the physical dimensions of the replacement cable and to the proper size fittings.

FITTINGS

Stuffing Tubes

Stuffing tubes (fig. 3-8A, B, and C) are used to provide for the entry of electric cable into splashproof, spraytight, submersible, and explosion-proof equipment enclosures. Cable clamps, commonly called box connectors (shown in figure 3-9), may be used for cable entry into all other types of equipment enclosures, except that top entry into these enclosures shall be made dripproof through stuffing tubes or cable clamps sealed with plastic sealer.

Below the main deck, stuffing tubes are used for cable penetrations of watertight decks, watertight bulkheads (fig. 3-10), and watertight portions of bulkheads that are watertight only to a certain height. Above the main deck, stuffing tubes are used for cable penetrations of (1) watertight or airtight boundaries; (2) bulkheads designed to withstand a waterhead; (3) that portion of bulkheads below the height of the sill or coaming of compartment accesses; (4) flametight or gastight, or watertight bulkheads, decks, or wiring trunks within turrets or gun mounts; and (5) structures subject to sprinkling.

Stuffing tubes are made of nylon, steel, brass, or aluminum alloys. Nylon tubes have very nearly replaced metal tubes for cable entry to equipment enclosures. Cable penetration of bulkheads and decks using nylon stuffing tubes is limited for use above the watertight level of a vessel. The watertight level is the highest expected water level (determined by the Bureau of Ships studies of stability and reserve buoyancy) and is indicated on the applicable ship's plans. The nylon tube

11328

Figure 17-15.—A-scan sweep, schematic diagram.

antenna, as shown in figure 17-16. It works best under conditions where the antenna scans a sector of less than 180°, but it can be employed in a situation where a 360° area is scanned.

Range is usually presented vertically by the use of a conventional sweep circuit. Refer to the B-scope block diagram in figure 17-17. The scope presentation may be created by either magnetic or electrostatic deflection. Since electrostatic deflection is usually employed, the final amplifiers are operated push-pull to gain the advantage of good sweep linearity.

Azimuth is presented horizontally by the use of a potentiometer that is mechanically connected to the antenna. The output of the potentiometer controls the horizontal push-pull amplifiers which in turn controls the horizontal deflection.

The intelligence is presented on the indicator by intensity-modulating the sweep. The antenna scanning speed is approximately one scan per second, whereas the sweep speed is at the PRF rate; therefore, the intelligence will also have range and bearing.

Sweep Circuit Theory

The master timing pulse (MTP) is often developed by the transmitter itself so that exact synchronization is possible with a minimum of circuitry. As shown in figure 17-18, it is coupled through C1 to the grid of V6. Inspection should reveal that V6 and V7 comprise

1130

Figure 3-5.—Cable runs with protective casings.

11330

11330

77.7

Figure 3-7.—Concentric pipe enclosure cable installation.

is a lightweight, positive-sealing, noncorrosive stuffing tube, which requires only minimum maintenance for the preservation of watertight integrity (fig. 3-11). The watertight seal between the entrance to the enclosure and nylon body of the stuffing tube is made with a neoprene "O" ring, which is compressed by a nylon locknut (fig. 3-12A). A grommet type, neoprene packing is compressed by a nylon cap to accomplish a watertight seal between the body of the tube and the cable. Two slip washers act as compression washers on the grommet as the nylon cap of the stuffing tube is tightened. Grommets of the same external size, but with different sized holes for the cable, are available. This allows a single-size stuffing tube to be used for a variety of cable sizes, and makes it possible for nine sizes of nylon tubes to replace 23 sizes of aluminum, steel, and brass tubes.

The nylon stuffing tube is available in two parts. The body "O" ring, locknut, and cap comprise the tube; and the rubber grommet, two slip washers, and one bottom washer comprise the packing kit.

A nylon stuffing tube that provides cable entry into an equipment enclosure is applicable to both watertight and nonwatertight enclosures (fig. 3-11A). Note that the tube body is inserted

11331

77.8

Figure 3-9.—Cable clamps.

access plate of expanded metal or perforated sheet metal (fig. 3-15A). Stuffing tubes are not required with riser boxes for cable passage through nonwatertight decks (fig. 3-15B).

The minimum spacing of holes for stuffing tubes and kickpipes is indicated in table 3-2. Tube sizes indicated are for metal tubes. For nylon tubes, the spacing is the same as for a metal tube of comparable size.

Cable Supports

The single cable strap is the simplest form of cable support. The cable strap is used to secure cables to bulkheads, decks, cable hangers, fixtures, etc. (fig. 3-16). The one-hole cable strap (fig. 3-16A) may be used for cables not exceeding five-eighths of an inch in diameter. The two-hole strap (fig. 3-16B) may be used for cables over five-eighths of an inch in diameter.

A more complex cable support is the cable rack, which consists of the cable hanger, cable strap, and hanger support (fig. 3-17). The types of cable straps are (1) contour straps, (2) semicontour straps, and (3) cable bands. The

11334
11333

BULKHEAD WITH INSULATION

BULKHEAD WITHOUT INSULATION

77.9

Figure 3-10.—Stuffing tubes on watertight bulkheads.

contour and semicontour straps are illustrated in figure 3-17A. The cable band is illustrated in figure 3-17B. Contour straps do not require the special grouping (by size) of cables that the use of either semicontour straps or cable bands entails. However, contour straps are more difficult to fabricate than semicontour straps, and cable bands are the simplest of the three to install because they do not require preforming.

Cable bands require hangers, which are designed to contain the banding without damaging it. The one-hole hanger (fig. 3-18) is available in sizes to accommodate one or more cables up to 2 inches in diameter. The two-hole hanger (fig. 3-19) ranges in width from 3 inches to

11334

A

77.11

Figure 3-12.—Nylon stuffing tube grounded installation.

B

77.10

Figure 3-11.—Typical nylon stuffing tube installations.

a maximum of 15 inches. For all applications, the width of the banding hanger must not be less than the overall width of the cables that it is intended to support.

Banding material is five-eighths of an inch wide, and may be zinc-plated steel, corrosion resistant steel or aluminum, depending on the requirements of the installation. Apply banding material in the manner shown in figure 3-20. Apply one turn of banding for a single cable less than one inch in diameter (fig. 3-18). Apply two turns of banding for single cables of one inch or more in diameter and for a row of cables (fig. 3-19). Apply three turns of banding for partially loaded hangers where hanger width exceeds the width of a single cable or a single row of cable by more than one-half inch (fig. 3-20). Add ferrules (fig. 3-19B) before applying banding material to partially loaded hangers. The application of banding material is illustrated in figure 3-20. A steel band of 0.015 inch thick may be used for cable bands, except when the weight of the cables is supported by the band, and any cable in the row is 2 inches or more in diameter. Then a steel band 0.020 inch thick must be used. An aluminum band 0.025 inch thick may be used where cables are less than 2 inches in diameter, and cable hangers are on centers no greater than 16 inches. For weatherdeck installations, use corrosion resistant steel band with copper armored cables; zinc-coated steel with steel armor; and aluminum with aluminum armor.

Cables must be supported so that the sag between supports, when practicable, will not exceed one inch. Five rows of cables may be supported from an overhead in one cable rack, and two rows of cables may be supported from a bulkhead in one cable rack. As many as 16 rows of cables may be supported in main cableways, in machinery spaces and boiler rooms. Not more than one row of cables shall be installed on a single hanger.

11[illegible]11

77.12

Figure 3-13.—Typical kickpipe installations.

The spacing of simple cable supports, such as those shown in figures 3-16 and 3-18 must not exceed 32 inches center to center. Spacing of the more complex supports, such as cable racks for main cableways, depends on the requirements of the installation but must not exceed 32-inch centers.

CABLE MARKINGS

Metal tags embossed with the cable designation are used to identify all permanently installed shipboard electrical cables. These tags, when properly applied, afford easy identification of cables for purposes of maintenance and replacement.

Two systems of cable marking (the old and the new) may be found aboard naval vessels. The old system used the color of the tag to denote cable classification and the following letters to designate power and lighting cables for the different services:

C—Interior communications
D—Degaussing
F—Ship's service lighting and general power
FB—Battle power
G—Fire control
MS—Minesweeping
P—Electric propulsion
R—Radio and radar
RL—Running, anchor, and signal lights
S—Sonar
FE—Emergency light and power

113361

77.13

Figure 3-14.—Watertight riser box weatherdeck installations.

Other letters and numbers were used with these basic letters to further identify the cable and complete the designation. Typical marking of a power system for successive cables from a distribution switchboard to load would be as follows: feeder, FB-411; main, 1-FB-411; submain, 1-FB-411A; branch, 1-FB-411A1; and subbranch, 1-FB-411-A1A. The feeder number, 411, is indicative of the system voltage. The feeder numbers for a 117- or 120-volt system would range from 100 to 199; for a 220-volt system, from 200 to 299; and for a 450-volt system, from 400 to 499. The exact designation for each cable is given on the electrical wiring plans of each vessel.

The new system for marking power and lighting cable indicates the source and, where practicable, the destination of the cable. Therefore, a thorough knowledge of the system for numbering electrical machinery and equipment aboard ship is necessary to fully understand the new system of cable marking. Except as otherwise specified in this chapter, the general rule for numbering machinery and equipment is used for numbering similar units of electrical machinery or equipment.

The general rule for numbering machinery and equipment states, in effect:

1. All similar units in the ship comprise a group, and each group is assigned a separate series of consecutive numbers beginning with 1.
2. Numbering begins in the lowest foremost starboard compartment, and the next compartment selected is to port of the first if it contains similar units; otherwise the next aft on the same level.
3. Proceeding from starboard to port and from forward to aft, the numbering procedure continues until all similar units on the same level have been numbered; then continues on the next upper level, and so on, until all similar units on all levels have been numbered.
4. Within each compartment, the numbering of similar units proceeds from starboard to port, forward to aft, and from a lower to a higher level.

Switchboards or switchgear groups supplied directly from ship's service generators are designated 1S, 2S, and so on as necessary to designate all ship's service switchboards. Switchboards supplied directly by emergency generators are designated 1E, 2E, and so on, as necessary to designate all emergency switchboards. Switchboards for special frequency (other than the frequency of the ship's service system) have a-c generators designated 1SF,

11337

Figure 3-15.—Interior riser box installations. 77.14

2SF, and so on, as necessary to designate all special frequency switchboards. Switchboards for coolant-pumping power generators are designated 1SC, 2SC, and so on, as necessary to designate all such switchboards. These designations are used only where the coolant-pumping power generators are separate from the ship's service generators.

Sections of a switchgear group other than the generator section are designated by an additional suffix letter starting with the letter, A, and preceeding in alphabetical order from left to right (it is assumed that the viewer is facing the front of the switchgear group). See switchgear group Nos. 4S and 6S (figs. 3-21 and 3-22), respectively.

Some large naval vessels are equipped with zone control, a system of ship's service distribution wherein the ship is divided into areas generally coinciding with fire zones, as dictated by the damage control plan of the ship. Power is distributed within each zone from load center

11338

Figure 17-16. —B-scan presentation.

Figure 17-17. —Block diagram of a B-scope system.

1131

77.15

Figure 3-16.—Single cable strap applications.

switchboards located within the zone. Load center switchboards and miscellaneous switchboards for ship's service distribution systems on vessels with zone control are given identification numbers, the first digit of which indicates the zone and the second digit the number of the switchboard within that zone, determined in accordance with the general rule for numbering machinery (fig. 3-22).

Load center switchboards and miscellaneous switchboards that are used on other than ship's service systems, all load center switchboards and miscellaneous switchboards for ship's service nonzonal distribution, and all distribution panels and bus transfer equipment are given identification numbers made up of either two or three parts in sequence, and each part is separated by hyphens. The first part indicates the vertical level, at which the unit is normally accessible, by deck or platform number. The second part indicates the longitudinal location of the unit by frame number. For duplicate units on the same deck and frame, the third part indicates the transverse location by the assignment of consecutive odd numbers for centerline and starboard locations and consecutive even numbers for port locations. The numeral 1 indicates the lowest centerline (or centermost, starboard) component. Consecutive odd numbers are assigned components as they would be observed first as being above, then outboard of the preceding component. Consecutive even numbers similarly indicate components on the port side. For example, a distribution panel with the identification number, 1-142-2, will be located on the main deck at frame 142, and will be the first distribution panel on the port side of the centerline at this frame on the main deck.

Except for the purpose of designating power cables between generators and switchboards, generators (except motor generators) are numbered to correspond to the numbering of the prime mover.

The power cables between generators and switchboards are labeled in accordance with the generators' designation. When only one generator supplies a switchboard, the generator will have the same number as the switchboard plus the letter G. Thus, 1SG denotes one ship's service generator that supplies number one ship's service switchboard. When more than one ship's service generator supplies a switchboard, the first generator determined in accordance with the general rule for numbering machinery will have the letter A, immediately following the designation; the second generator that supplies the same switchboard will have the letter B, and this procedure will be continued for all generators that supply the switchboard, and then repeated for succeeding switchboards. Thus, ISGA and ISGB denote two ship's service generators that supply ship's service switchboard 1S.

In figure 3-21 the cables from generators 3SGA and 3SGB to 3S are labeled 3SGA-4P-3S and 3SGB-4P-3S, respectively.

Motor generators, transformers, and rectifiers are designated by standard symbols, each made up of two capital letters and a numeral. The letters used are MG for motor generators, TF for transformers, and RT for rectifiers. The numeral gives the location of the equipment on the ship, in accordance with the general rule of numbering from forward aft and from starboard to port.

77.16

Figure 3-17.—Cables installed in a cable rack.

11340

77.17

Figure 3-18.—Single cable band.

77.18

Figure 3-19.—Two-hole banding hanger.

The new designation system for power and lighting cables consists of three parts in sequence: source, voltage and service, and, where practicable, destination. These parts are separated by hyphens.

The letters used to designate the different services are:

C—Interior communication
D—Degaussing
G—Fire control
K—Control power
L—Ship's service lighting
N—Navigational lighting
P—Ship's service power
R—Electronics
CP—Casualty power
EL—Emergency lighting
EP—Emergency power
FL—Night flight lights
MC—Coolant pump power
MS—Minesweeping
PP—Propulsion power
SF—Special frequency power

In the new system, voltages below 100 volts are designated by the actual voltage—for example, 24 for a 24-volt circuit. The number, 1, is used to indicate voltages between 100 and 199; 2, for voltages between 200 and 299; 4, for voltages between 400 and 499; and so on, through 50 for voltages between 5000 and 5999. For a three-wire (120/240), d-c system or a four-wire, 3-phase system, the number used will indicate the higher voltage.

The destination of cable beyond panels and switchboards is not designated except that each circuit alternately receives a letter, a number, a letter, and a number, progressively, every time that it is fused. The destination of power cables to power consuming equipment is not designated, except that each cable to such equipment receives a single-letter alphabetical designation, beginning with the letter, A.

Where two cables of the same power or lighting circuit are connected in a distribution panel or terminal box, the circuit classification will not be changed. However, the cable markings will have a suffix number (in parentheses) indicating the cable section—for example, circuit (4-168-1)-4P-A(1) (fig. 3-21).

For cables that have a normal and an alternate or emergency feeder, the source designation contains (first) the source of the normal feed and (second, separated by a slant line) the designation of the source of the

alternate or emergency feed—for example, (5-190-1)/3E-1SF-C(2) in figure 3-22.

EQUIPMENT MARKING

All distribution panels and bus transfer equipment are provided with cabinet information plates. These plates contain the following information in the order listed: (1) the name of the space, apparatus, or circuits served; (2) the service (power, lighting, electronics, etc.) and basic location number; and (3) the supply feeder number. For example,

CREW LIVING SPACE, FRAMES 107-149
FIRST PLATFORM
LIGHTING PANEL 4-108-2
2S-4L-(4-108-2).

If a panel contains two or more sets of buses and each set is supplied by a separate feeder, the number of each feeder will be indicated on the identification plate.

Distribution panels are provided with circuit information plates adjacent to the handle of each circuit breaker or switch. These plates contain the following information in the order listed: (1) the circuit number, (2) the name of the apparatus or circuit controlled, (3) the location of apparatus or space served, (4) the circuit load amperes, and (5) the circuit breaker element or fuse rating. Red markers are attached to circuit information plates to indicate vital circuits. Information plates for circuit breakers supplying circle W and circle Z class ventilation systems contain, in addition to the red marker, the class designation of the ventilation system supplied. Information plates without markings are provided for spare circuit breakers mounted in distribution panels. Panel switches controlling circuits that are deenergized during darkened ship operations are marked DARKENED SHIP. The ON and OFF position of these switches are marked LIGHT SHIP and DARKENED SHIP, respectively.

Circuit information plates are provided inside fuse boxes (adjacent to each set of fuses) and indicate the circuit controlled; the phases, or polarity; and the ampere rating of the fuse.

CONDUCTOR IDENTIFICATION

Each terminal and connection of rotating a-c and d-c equipment, controllers, and transformers is marked with standard designations. This may be accomplished with synthetic resin tubing or fiber wire markers located as close as practicable to equipment terminals, with fiber tags near the end of each conductor, or by stamping the terminals.

Individual conductors may also be identified by a system of color coding. Color coding of individual conductors in multiconductor cable is in accordance with color coding tables contained in chapter 9005(40), Bureau of Ships Technical Manual. The color coding of conductors in power and lighting cables is shown in table 3-4. Neutral polarity, where it exists, is always identified by the white conductor.

Table 3-4.—Color Code for Power and Lighting Cable Conductor

System	No. of Conductors in Cable	Phase or Polarity	Color Code
3-phase a-c	3	A B C	Black White Red
	2	AB	A, black B, white
	2	BC	B, white C, black
	2	AC	A, black C, white
3-wire d-c	3	+ ± -	Black White Red
	2	+ and ±	+, black ±, white
	2	± and -	±, white -, black
	2	+ and -	+, black -, white
2-wire d-c	2	+ -	Black White

U49345

END SEALS

Where it is possible for the sheath of shipboard electric cable to act as a conduit in carrying quantities of water from a flooded to an unflooded space beneath the watertight level of a vessel, the cable ends must be sealed to prevent the entrance and discharge of water from cable ends. Because the presently approved method of sealing cable ends requires special equipment not available to shipboard personnel, the installation of cables that require cable end seals should not be attempted by the Electrician's Mate, except in an emergency.

Exercise care when working around cables and switchboards to prevent damage to cable end seals. Make frequent inspections for visual evidence of defects in the seals. If any holes are found in the synthetic tubing used at end seals, make a temporary repair by wrapping the tubing tightly with several layers of synthetic tape (half lapped), with a serving of cord over each end of the tape. Other defects, which are noted, should be repaired as effectively as available materials and equipment permit. All cable end seals to which temporary repairs have been made and all cables that may require end sealing must be tagged and scheduled for permanent repair at a naval shipyard or shore base at the earliest opportunity.

Type SGA and other currently manufactured cables that have a waterproofing impregnant between the strands and in the material between the conductors and the inside of the sheath are not completely watertight. Cable-end sealing is required for these cables except in interior communications and weapons control systems where cable types TTHFWA, MSCA, and SGA sizes 9 and smaller are employed.

CABLE CONNECTIONS

Cable Ends

When connecting a newly installed cable to a unit of electrical equipment, the first thing to determine is the proper length of the cable. To do this, form the cable run from the last cable support to the equipment by hand, allowing sufficient slack and radius of bend to permit repairs without renewal of the cable. Carefully estimate where the armor on the cable will have to be cut to fit the stuffing tube (or connector), and mark the location with a piece of friction tape. In addition to serving as a marker, the tape will prevent unraveling and hold the armor in place during cutting operations.

Determine the length of the cable inside the equipment, using the friction tape as a starting point. Whether the conductors go directly to a connection or form a laced cable with breakoffs, carefully estimate the length of the longest conductor, add approximately 2 1/2 times its length, and mark this position with friction tape. The extra cable length will allow for mistakes in attaching terminal lugs and possible rerouting of the conductors inside the equipment. The length of the cable is now known and it can be cut.

The armor must be removed next. This may be accomplished by using a cable stripper of the type shown in figure 3-23. Care must be taken not to cut or puncture the cable sheath where the sheath will contact the rubber grommet of the nylon stuffing tube (fig. 3-11). If either a metal stuffing tube or cable connector (fig. 3-13) is used, allow the cable (with armor) to extend at least one-eighth of an inch through the tube.

Next, remove the impervious sheath, starting a distance of at least 1 1/4 inch (or as necessary to fit the requirements of the nylon stuffing tube) from where the armor terminates. The cable stripper should be used for this job. Do not take a deep cut because the conductor insulation can be easily damaged. Flexing the cable will help separate the sheath after the cut has been made. Clean the paint from the surface of the remaining impervious sheath exposed by the removal of the armor. This paint is conducting. It is applied during manufacture of the cable and passes through the interstices of the armor onto the sheath. Once the sheath has been removed, the cable filler can be trimmed with a pair of diagonal cutters.

The proper method of finishing and protecting cable ends that do not require end sealing is shown in figure 3-24. For cables entering enclosed equipment (connection boxes, outlet boxes, fixtures, etc.) the method shown in figure 3-24A, should be used. An alternate method (when synthetic resin tubing is not readily obtainable) is to apply a coat of air drying insulation varnish to the insulation of each conductor as well as to the crotch of the cable. The end of the insulation on each conductor is reinforced and served with treated glass cord, colored to indicate proper phase marking. For cables entering open equipment (switchboards, etc.) the method shown in figure

611846

77.22

Figure 3-23.—Cable strippers.

3-24B, should be used. An alternate method is to wrap each conductor tightly with one layer of synthetic tape (half lapped) and serve with cord as in the tubing method. Apply tape, air-drying varnish, and serve the crotch and part of the cable for a distance about 2 inches back of the crotch.

Conductor Ends

Wire strippers (fig. 3-25) are used to strip insulation from the conductors. Care must be taken to avoid nicking the conductor standing while removing the insulation. Side, or diagonal, cutters should not be used for stripping insulation from conductors.

Conductor surfaces must be thoroughly cleaned before terminals are applied. After barring the conductor end for a length equal to the length of the terminal barrel, clean the individual strands thoroughly and twist them tightly together. Solder them to form a neat, solid terminal for fitting either approved clamp-type lugs or solder type terminals. If the solder type terminal is used, tin the terminal barrel and clamp it tightly over the prepared conductor (before soldering) to provide a solid mechanical joint. Conductor ends need not be soldered for use with solderless type terminals applied with crimping tool. Do not use a side, or diagonal, cutter for crimping solderless type terminals.

29.226

Figure 3-24.—Protecting cable ends.

11347

1.24

Figure 3-25.—Mechanical wire strippers.

Solderless type terminals may be used for all lighting, power, interior communications, and fire control applications, except with equipment provided with solder type terminals by the manufacturer, and with wiring boxes or equipment in which electrical clearances would be reduced below minimum standards by the use of the solderless type terminal.

For connection under a screwhead where a standard terminal is not practicable, an alternate method can be used. Bare the conductor for the required distance and thoroughly clean the strands. Then twist the strands tightly together, bend them around a mandrel to form a suitable size loop (or hook where the screw is not removable), and dip the prepared end into solder. Remove the end, shake off the excess solder, and allow it to cool before connecting it.

After the wiring installation has been completed, the insulation resistance of the wiring circuit must be measured with a megger or similar (0-100 megohm, 500 volt d-c) insulation resistance measuring instrument. Do not energize a newly installed, repaired, or modified wiring circuit without first ascertaining (by insulation tests) that the circuit is free of short circuits and grounds.

Small refrigerators, drinking fountains, coffee makers, and bracket fans are plugged into receptacles connected directly to the ship's wiring. To remove stress from the equipment terminal block and its connected wiring, rigidly clamp the cable to the frame of the equipment close to the point where the cable enters the equipment.

Lacing Conductors

Conductors within equipment must be kept in place in order to present a neat appearance and facilitate tracing of the conductors when alterations or repairs are required. When conductors are properly laced, they support each other and form a neat, single cable.

The most common lacing material is waxed cord. The amount of cord required to single lace a group of conductors is approximately 2 1/2 times the length of the longest conductor in the group. Twice this amount is required if the conductors are to be double laced.

Before lacing, lay the conductors out straight and parallel to each other. Do not twist them together because twisting makes conductor lacing and tracing difficult.

A shuttle on which the cord can be wound will keep the cord from fouling during the lacing operations. A shuttle similar to the one shown in figure 3-26 may easily be fashioned from aluminum, brass, fiber, or plastic scrap. Rough edges of the material used for the shuttle should be smoothed to prevent injury to the operator and damage to the cord. To fill the shuttle for single lace, measure the cord, cut it, and wind it on the shuttle. For double lace, proceed as before, except double the length of the cord before winding it on the shuttle, and start the ends on the shuttle in order to leave a loop for starting the lace.

Some installations, however, require the use of twisted wires. One example is the use of "twisted pairs" for the a-c filament leads of certain electron tube amplifiers to minimize radiation of their magnetic field, thus preventing annoying hum in the amplifier output. The EM should duplicate the original layout, when replacing such twisted leads, and when relacing any wiring harness.

Single lace may be started with a square knot and at least two marling hitches drawn

5.138

Figure 3-26.—A lacing shuttle.

Figure 17-18.—B-scan sweep, schematic diagram.

a single-kick multivibrator in which V7 in statically conducting and V6 is cut off by the voltage developed across R18. The pulse causes V6 to conduct and V7 is then cut off by normal multivibrator action. By itself, the multivibrator would return to the static condition upon discharge of C2 through R20, but this would take a very long time in respect to the PRT. As will be seen later, this is not permitted to happen. The negative square wave developed in the plate circuit of V6 is coupled through C3 to the grid of V8, the sweep generator, cutting it off. With V8 cut off, C4, the sweep capacitor, charges through R27, the sweep resistor. R26 and R28 are alternate sweep resistors and would be used to obtain different sweep lengths. As C4 charges, the rising voltage is applied to the grid of V9, a cathode follower, and a sawtooth is developed across R23 and R24 which are in parallel.

The portion of this voltage picked off by the arm of R24 is coupled through C5 to the grid of V4. V4 and V5 form a grounded-grid paraphase amplifier. These tubes share a common cathode resistor, R11; and as the current increases in one tube, it decreases in the other. Hence, a rising grid voltage from R24 on the grid of V4 will cause the plate voltage of V4 to decrease and the plate voltage of V5 to increase. These two voltages, coupled to the vertical deflection plates of the indicator V3, cause vertical deflection of the electron spot.

1132

tight. Details of the square knot and the marling hitch are shown in figure 3-27. Do not confuse the marling hitch with a half hitch. In the marling hitch, the end is passed over and under the strand (step 1, fig. 3-27). After forming the marling hitches, draw them tight against the square knot (step 2, fig. 3-27). The lace consists of a series of marling hitches evenly spaced at one-half inch to one-inch intervals along the length of the group of conductors, as indicated in step 3.

When dividing conductors to form two or more branches, follow the procedure illustrated in figure 3-28. Bind the conductors with at least six turns between two marling hitches, and continue the lacing along one of the branches (fig. 3-28A). Start a new lacing along the other branch. To keep the bends in place, form them in the conductors before lacing. Always add an extra marling hitch just prior to a breakout (fig. 3-28B).

Double lace is applied in a manner similar to single lace, except that it is started with the telephone hitch and is double throughout the length of the lacing (fig. 3-29). Double as well as single lace may be terminated by forming a loop from a separate length of cord and using it to pull the end of the lacing back underneath a serving of approximately eight turns (fig. 3-30).

Lace the spare conductors of a multiconductor cable separately, and secure them to active conductors of the cable with a few telephone hitches. When two or more cables enter an enclosure, each cable group should be laced separately. When groups parallel each other, they should be bound together at intervals with telephone hitches (fig. 3-31).

Conductor ends (3000 cm or larger) should be served with cord to prevent fraying of the insulation (fig. 3-32). When conductor ends are served with glass cord colored for phase marking, the color of the cord should match the color of the conductor insulation.

Grounded Receptacles

Aboard naval vessels, grounded receptacles (fig. 3-33) are used with grounded plugs and portable cables having a ground wire, which grounds the metallic case and exposed metal parts of portable tools or equipment to the ship's structure when the plugs are inserted in the receptacles. The ground wire prevents the occurrence of dangerous potentials between

12.247

5.139

Figure 3-31.—Binding cable groups with the telephone hitch.

the tool or equipment housing and ship's structure, and thus protects the user from shock.

The grounded receptacles most widely used aboard naval vessels have metal enclosures, which are connected internally to the ground terminal of the receptacle. Grounding the enclosures will ground the grounded terminal. Grounded receptacles with plastic enclosures are in use aboard some vessels, and in these receptacles the grounded terminal is connected to ground through a conductor. The cross-sectional area of the conductor used to connect the grounded terminal to ground must be greater than that of the conductors that supply such a receptacle.

Whenever a grounded receptacle is installed, repaired, or modified in any way, a test must be made to determine whether the connections are correct. To make this test, use a voltmeter or voltage tester to test the voltage across the line terminals. Full line voltage should be indicated. Next, test the voltage between the ground terminal in the receptacle and some metallic part of the ship's structure that is not

5.140.2

Figure 3-32.—Serving conductor ends.

5.81

Figure 3-33.—Watertight grounded receptacle.

a part of the receptacle. This voltage should be zero. After the voltage from the ground terminal to ground has been measured and found to be zero, (deenergize the circuit), use an ohmmeter or other low-reading (zero to a few ohms), resistance-measuring instrument such as multimeter or analyzer to measure the resistance from the ground terminal to ground. This resistance value should be not over 0.1 ohm. However, the meters generally available will not read this low. As a rough, practical check, therefore a reading of not more than one ohm may be considered as reasonable assurance that the ground path is satisfactory. Unless all of the preceding conditions are satisfied, the receptacle is not correctly connected and constitutes a safety hazard.

To determine the safety of grounded receptacles, inspect and test them. The following procedures should be followed in making monthly routine ground-continuity tests of each installed receptacle.

1. Plug in any small 115-volt portable electric tool into the receptacle to be tested.

2. Secure one ohmmeter lead to the metal of the tool housing and its other lead to the ship's hull.

3. The ohmmeter reading must be less than one-tenth (0.10) ohm to indicate a satisfactory grounding from the tool housing through the plug and receptacle to the ship's hull.

Note: Meters that will read 0.1 ohm are not commonly available, therefore a reading of not more than one ohm is reasonable assurance that the ground connection is satisfactory.

4. Unsatisfactory receptacles should be immediately repaired or tagged to indicate they must not be used.

A record book should be kept, giving the location of all grounded receptacles and the dates on which they are inspected and tested. The inspection of the receptacle should ascertain that:

1. The phenolic polarity pin in the insert of the receptacle is in place (fig. 3-33B).

2. The receptacle cover is placed so that the pointed metal polarity tab (brazed to the cover) is superimposed over the phenolic polarity pin within the receptacle.

3. The phenolic plug-guide insert in the aperture of the receptacle cover is firmly in place (fig. 3-33C). Where the inserts are missing, replace the entire cover. Correct loose inserts by cementing them.

4. The protective cap with rubber gasket is properly attached by chain to the receptacle cover (fig. 3-33D). Spraytight, watertight, and submersible receptacles must be kept covered when plugs are not inserted.

Present practice is to standardize on grounded 125/250-volt plugs and receptacles on all surface vessels and submarines.

On the older ships single 125-volt, 10-ampere, single-phase a-c (or 2-wire d-c) stub

type (like fig. 3-33) watertight receptacles are used for all applications except for electric shavers and some electronic applications. For electric shavers and some electronic applications, double 125-volt, 15-ampere, single-phase a-c (or 2-wire d-c) bladed type receptacles are used.

On new ships, general purpose grounded receptacles are provided as follows:

1. Double 125-volt, 15-ampere, single-phase a-c (or 2-wire d-c) bladed type receptacles are used for all below-deck applications.
2. Single 125-volt, 15-ampere, single-phase a-c (or 2-wire d-c) watertight bladed type receptacles are installed on radar platforms and open bridges for use of electronic test equipment.
3. Single 125-volt, 10-ampere, single-phase a-c (or 2-wire d-c) stub type submersible receptacles are used for topside and for applications where a watertight receptacle is required, except on radar platforms and open bridges.

Receptacles are required to be so spaced as to permit the use of portable tools at any place on the ship without requiring more than 50 feet of flexible cable between the tool and receptacle. The reason is twofold (1) economy: closer spacing of receptacles is wasteful (2) safety: greater spacing of receptacles results in excessively long and thus a higher resistance grounding conductor which may not protect the operator from shock if portable equipment develops derangement which places potential on the metal case.

Receptacles installed for specific applications such as radiant heaters are included in the receptacle spacing to meet the 50 foot rule and therefore may be considered as available for portable tools.

If additional receptacles are required to meet the 50 foot rule, care should be exercised to ensure that added receptacles do not result in overloading the circuits.

Grounded Plugs

The electric cable used with portable electric tools and equipment must be provided with a distinctly marked grounding conductor in addition to the conductors for supplying power. Up to this time (except for a few cases where black was used), red was used for the grounding conductor in three-conductor cables, and green in four-conductor cables. Today, Navy specifications require that green be used for the grounding conductor in cables for all new portable tools and equipment. However, no change should be made in equipment (now on board ship) which has a cable with a grounding conductor color coded in conformity with past practice. Such equipment should be used until cable replacement becomes necessary. An average of eight sailors are killed each year by electric shock. A frequent cause is that the grounding conductor was connected to a live terminal. To help avoid this, it will be easy to remember that permanently mounted electrical equipment (metal boxes, panels etc) are grounded to the ships structure by their mounting bolts. All that the grounding conductor does, regardless of its color, is simulate the mounting bolts of permanent equipment; namely; joins the metal case of portable electric equipment to the ship's hull.

In replacing cable on portable single phase a-c or 2-wire d-c equipment the three-conductor flexible cable types THOF should be used. The four-conductor FHOF type cable should be used in replacing cables on three-phase portable equipment.

The end of the grounding conductor, which is within the tool (or equipment), should be connected to the metal housing, and the other end should be connected to the grounding blade of a grounded plug (fig. 3-34). Make certain that the ground connection is correctly made. If the

5.13

Figure 3-34.—Grounded plug.

grounding conductor is inadvertently connected to a line contact of the plug, a dangerous potential that is almost certain to be fatal to the operator will be placed on the metal equipment casing. To guard against such an occurrence, the connections should be tested after they have been made. Recently plastic cased tools (drills, sanders, grinders, etc.) have been developed for shipboard use to eliminate the risk of electric shock. In these tools the shafts and chucks are isolated electrically from the drive motors. Do not replace the two-conductor cable on plastic cased tools with a three conductor cable if the plastic cased tool has an information plate reading "grounding not required".

Portable Equipment

Prior to issue of any portable metal-cased electrical equipment (including extension cords) the attached cable with plug should be examined visually to ensure satisfactory condition. (Tears, chafing, exposed insulated conductors and damaged plugs are causes for cable or plug replacement.) Also, prior to each issue, that item should be plugged into a dummy (or deenergized) receptacle and tested for resistance (should be less than 0.1 ohm) from equipment metal housing to ship's structure. During this test, work the flexible cable with a push-pull twisting-bending motion where it enters plug and equipment. The following conditions will ensure the grounding circuit is always below 0.1 ohm.

The length of flexible cable for portable equipment should not exceed 25 feet, except the cable for portable heaters should be as required.

The length of extension cords should also be limited to 25 feet. If additional extensions are used and the length of the cable exceeds 50 feet from receptacle to portable tool, a separate (additional) grounding conductor must be connected from the tool's housing to the ship's hull.

The cables of portable equipments kept outside the electric shop must be tested weekly. A list of those equipments must be established. The following items should be included: portable hand-held electric tools that are permanently charged out or on loan to other shipboard departments or divisions; electric equipment which is frequently touched, such as hot plates, coffee makers, toasters, portable vent sets, movie projectors, and office equipment. Electric equipment which is infrequently touched, such as bulkhead mounted fans energized from receptacles, are recommended for testing once a year.

After making the preceding measurements for low resistance, WHILE STILL USING THE DEENERGIZED RECEPTACLE, connect one lead of a megger, or similar high-resistance measuring instrument to the metal case of the equipment and its other lead to either of the line terminals of the plug. Measure the resistance with the switch on the equipment in the ON position and also when it is in the OFF position. In both cases, the readings obtained will be normal insulation resistance (usually well in excess of 1 megohm) if the connections are correctly made. Repeat this procedure with the megger connected to the case of the equipment and the other line contact of the plug (or to each of the other line contacts if there are more than two). In each case the megger should read normal insulation resistance if the connections are properly made.

Two resistance-measuring instruments must be used for the foregoing test because one instrument (unless it has scales for both high and low resistance) will not give reliable results. This test should also be made on all portable equipment that has not previously been tested in this way, even though it may have been used previously without trouble. This test must be repeated weekly on all portable electrical equipment to ensure that the equipment remains in a safe condition. Instruct all personnel using the equipment not to attempt to reconnect the cable to the plug if it should ever be pulled out. This connection must always be made and tested by a competent Electrician's Mate.

Electrical equipment that is positively and adequately grounded through its mounting (such as bracket fans), or portable lights and other equipment having no exposed metal parts that may become energized may be fitted with a two-conductor repeated flexing service cable and a plug suitable for use with the grounded type receptacle. However, test to make sure that the natural grounding of the equipment is not blocked off in any way.

CASUALTY POWER CABLE

Suitable lengths of portable casualty power cables are stowed throughout naval vessels close to the locations where they may be needed for making temporary connections in the event

11353

the installed ship's service and emergency distribution systems are damaged. The casualty power system is completely described in chapter 10 of this training course. Only the portable cable is discussed here. Portable casualty power cables are equipped with metal tags, which indicate the length of the cable (in feet) and the location of the cable stowage rack (fig. 3-35).

Both ends of portable casualty power cable are made up in the same manner as shore power cable illustrated in figure 3-36 except that:

1. The outer sheath of the cable (step 1, fig. 3-36A) is removed from the cable for approximately 1 foot, or a sufficient distance to permit ready attachment to the casualty power bulkhead, riser, and switchboard terminals, and portable switches.

2. Ferrules (cable thimbles) of tubular copper material are attached to conductor ends instead of lugs (step 7, fig. 3-36B). The conductor insulation must be 3/8" from crimped copper ferrule at end of conductor (1 1/4" from extreme tip of ferrule). This permits full insertion of the tips of subject conductors into the bulkhead terminals and leaves no exposed copper.

3. Phase or polarity, as appropriate, of the conductors must be indicated by servings on the conductors. One serving of cotton cord indicates phase A, or positive polarity (black conductor); two separate servings indicate phase B, or neutral polarity (white conductor); and three separate servings indicate phase C, or negative polarity (red conductor). The servings on the conductors afford a means of identifying (by touch) the individual conductors when illumination is insufficient for visual identification.

Portable casualty power cables should be rigged only when required for use or for practice in rigging the casualty power system. At all other times, they should be stowed in the cable rack indicated on the cable tag. When portable casualty power cables are rigged, connections should be made from the load to the supply to avoid handling energized cables.

Casualty power cables are a very important part of the ship's equipment. Each year the cables and terminal connections should be closely inspected and tested.

On ships that have the planned maintenance system (PMS) installed the inspection would be a scheduled routine. If you as an EM3, while checking the weekly work schedule, find the division PO has assigned you and Jones EMFN to accomplish A-1 on casualty power cables, proceed as follows. Remove MRC EL-12, A1 (fig. 3-37) from the file or cardholder in your

12.74

M R DESCRIPTION

1. Visually inspect casualty power cables and terminal connections.
2. Measure the insulation resistance of all bulkhead biscuits and risers.

TOTAL M/H: 32.0
ELAPSED TIME 16.0

SAFETY PRECAUTIONS

1. Test each biscuit with a voltage tester to insure it is de-energized before attempting any repairs.

TOOLS, PARTS, MATERIALS, TEST EQUIPMENT

1. Scribe
2. Flashlight
3. Sandpaper 4/0
4. Voltage tester
5. 500 volt megger

PROCEDURE

1. a. Remove cables from storage rack and flake out on deck.
b. Visually inspect the insulation for cuts, cracks, or chaffing.
c. Inspect all lugs for cleanliness and sound connections. Clean with 4/0 sandpaper.
d. Report any unusual condition to the leading petty officer.
e. Return all cables to the proper stowage.
f. Test each biscuit to insure it is de-energized. Visually inspect each connection to insure cleanliness. Clean as necessary. Remove foreign matter with a scribe.
g. Measure the insulation resistance to ground of each bulkhead biscuit and riser. Report any reading below meg-ohms to the leading petty officer.

LOCATION

98.176

Figure 3-37.—Maintenance Requirement Card (MRC).

shop. Read the card carefully, it tells what tools and material the job will require, safety precautions to observe, and procedures to follow. The total manhours the job should require will vary depending on your particular type ship. Upon completion of the job, return the MRC to its file and mark the job (x) on the weekly work schedule so that the division PO can see it is completed.

The same procedures for checking casualty power cables should be followed on ships that do not as yet have the PMS system installed.

After an exposure period of five years or more, the casualty power cable conductor insulation may have aged and lost its elasticity to the extent that it will crack open when bent during handling incident to emergency use. The best method of detecting overage insulation of the exposed ends of individual conductors is to sharply bend each conductor by hand. If no visual cracks develop, the insulation is satisfactory. If cracking is noted it should be reported to the leading petty officer. Cable ends with cracked insulation should be cut back and new terminals prepared in accordance with NavShips Technical Manual, chapter 9621, Section I.

The casualty power cables must be checked after any repairs to ensure that they are still of sufficient length to make connections at designated risers and equipments.

SHORE POWER CABLE

A shore terminal box is provided at a suitable weatherdeck location aboard ship. Portable cables from shore power or from a ship alongside can be attached to the shore terminal box to supply power to the ship's distribution system. This same connection can be used to supply power from the ship's service generators to a ship alongside. The shore power system is designed to handle only enough power to operate necessary machinery and provide illumination for habitability and the accomplishment of necessary work. Care must be exercised not to exceed the capacity of the system when it is in use.

Older type flexible shore power cables are connected to their shipboard terminal box(es) by bolted (fig. 3-36B) lugs. Later type cables have plug (fig. 3-36C) contacts which are plugged into 400-ampere (3-terminal) receptacles.

For a-c systems, the flexible shore power cables are 3-conductor, 400,000 cm (type THOF-400). These are rated 366-amp and 338-amp in ambient temperatures of 40° C and 50° C, respectively. Where practical for maintaining the best voltage regulation, several cables should be connected to limit each conductor's current below 250 amperes. However, all cables should be able to safely carry 400-ampere loads for 2 to 3 hours when the desired arrangement is not practical.

The lug ends of all shore-power cables (if not already prepared when received aboard ship) should be made up in the following manner:

1. Remove the outer sheath from the cable for approximately 2 feet, or a sufficient distance to permit ready attachment to the shore terminal box (step 1, fig. 3-36A). Do not damage the insulation of the individual conductors.
2. Taper the end of the outer sheath, starting about 1 inch back from the cut end (step 2, fig. 3-36A).
3. Apply a coat of air-drying, insulating varnish to the crotch of the cable and allow it to dry (step 3, fig. 3-36A).
4. Apply two layers of pressure-sensitive synthetic resin tape or friction tape (half-lap), starting about 2 inches back of the crotch and finishing about 2 inches in front of the crotch (step 4, fig. 3-36B).
5. Reinforce and seize the tape with a serving of treated glass cord, and coat the completed serving with air-drying insulating varnish (step 5, fig. 3-36B).
6. Apply a serving of treated glass cord, colored for phase marking (step 6, fig. 3-36B).
7. Attach lugs as furnished with the ship's shore terminal box (step 7, fig. 3-36B). Stamp the lugs to indicate the phase (A, B, C) or polarity (+, ±, -) of the conductors. The lug markings, the colored glass cord serving, and the color of the conductor should all agree with the phase and polarity code for light and power conductors (table 3-4).

The terminal connecting block, and terminals of the ship's shore terminal box must be plainly marked to indicate phase sequence, or polarity, as appropriate. For example, the terminal of the black conductor should be stamped (A) to indicate phase A; or stamped (+) to indicate polarity, as appropriate, and so on. The color code of cables should not be implicitly trusted because the conductors (from exposure) may become discolored or lose their original coloring.

When practicable, follow these procedures when connecting shore power cables.

1. Test the ship's shore terminal box for proper marking. Do this by energizing the shore terminal box from the ship's service generator. Check the phase sequence (a-c) markings by testing the terminals with a phase sequence indicator. Check polarity (d-c) markings by testing the terminals with a polarity-indicating voltage tester. An approved type phase-sequence indicator is shown in figure 3-38.

73.52
Figure 3-38.—Phase-sequence indicator.

This indicator consists of a miniature, 3-phase induction motor, which indicates phase sequence by the direction in which the rotor (moving element) turns. After it has been determined that the markings are correct, secure the ship's power to the shore terminal box by opening the ship's shore power switch. This switch should be tagged in the manner prescribed for tagging circuits (on which men are working) in the section of this chapter titled "Maintenance."

2. Rig the shore power cable and connect one end of it to the ship's shore terminal box. Make certain that the leads are properly connected in accordance with the terminal markings of the box.

3. Check the terminals on the shore connection with a voltage tester, and after it has been determined that they are energized, connect the other end of the shore power cable leads.

4. Energize the cable from the shore power supply, and test either phase sequence, or polarity, (depending on whether a-c or d-c). If the phase sequence, or polarity, matches that of the ship's power, the ship may safely switch to shore power. The procedure for switching to shore power is given in chapter 11.

Warning signs indicating the voltage of the cable should be attached to the shore power cable at intervals to warn personnel to keep clear of the cable. All connections must be tightly made to prevent damage to the terminals or leads as a result of overheating and arcing.

The procedures and precautions that follow apply to all portable cables as well as the shore power cables. Spliced portable cables are extremely dangerous and should not be used unless an emergency warrants the great risk involved. Portable cables must be of sufficient length to prevent their being subjected to longitudinal stresses and the need to be pulled taut to make connections. Current-carrying capacity must be ample for the expected power demand. The cable must be checked frequently to ascertain the degree of heating, and any cable that feels uncomfortably warm to the bare hand (placed outside the insulation) should be checked immediately for overloading. Interconnections between lengths of portable cable shall be made only on approved connection block or by other approved fittings that shall be suitably insulated and enclosed to eliminate all possible hazards from fire or shock to personnel.

Always support portable cables above decks, floor plates, and gratings. Never place them where they can be damaged by falling objects, by being walked on, or by contact with sharp corners or projections in the ship's hull or other objects. Where portable cables pass through doorways or hatches, provide steps to prevent cables from being pinched by a door or hatch cover.

CABLE MAINTENANCE

The primary purpose of electrical cable maintenance is to preserve the insulation resistance. Hence, it is important to know the insulating materials that are used in naval shipboard electrical equipment and the factors that affect insulation resistance.

INSULATION

The purpose of insulation on electric cables and equipment is to (1) isolate current-carrying conductors from metallic and structural parts, and (2) insulate points of unequal potential on conductors from each other. Normally, the resistance of such insulation should be sufficiently high to result in negligible current flow through or over its surface.

Air may be used as an insulator if a solid insulating material is used for support to maintain proper electrical clearance and creepage distances. The CLEARANCE distance is the shortest point to point distance in air between two bare (uninsulated) conductors or

between a bare conductor and ground. The CREEPAGE distance is the shortest distance between two bare (uninsulated) conductors, or between a bare conductor and ground, measured along the surface of the solid insulating material. Permissible clearance and creepage distances depend upon the voltage and current involved, the degree of enclosure, and the properties of the insulating material supporting the conductors. Minimum acceptable electrical clearance and creepage distances (in inches) are shown in tables contained in chapter 9005(40) of the NavShips Technical Manual.

The electrical insulating materials used in naval shipboard electrical equipment (including cables) are grouped according to their chemical composition; for example, class O, class A, class B, class C, class H, class E, and class T insulation.

Class O insulation consists of cotton, silk, paper, and similar organic materials when neither impregnated nor immersed in a liquid dielectric. Class O insulation is seldom used by itself in electrical equipment.

Class A insulation consists of (1) cotton, paper, and similar organic materials when they are impregnated or immersed in a liquid dielectric; (2) molded and laminated materials with cellulose filler, phenolic resins and other resins of similar properties; (3) films and sheets of cellulose acetate and other cellulose derivatives of similar properties; and (4) varnish (enamel), as applied to conductors.

Class B insulation consists of mica, asbestos, fiber glass, and similar inorganic materials in built-up form with organic binding substances, such as polyvinylacetal or polymide films. A small portion of class A materials may be used for structural purposes only.

Class H insulation consists of (1) mica, asbestos, fiber glass, and similar inorganic materials in built-up form with binding substances composed of silicone compounds or materials with equivalent properties; and (2) silicone compounds in the rubbery or resinous forms, or materials with equivalent properties. A minute proportion of class A materials may be used only where essential for structural purposes.

Class C insulation consists entirely of mica, glass, quartz, and similar inorganic material. Class C materials, like class O, are seldom used alone in electrical equipment.

Class E insulation is an extended silicone rubber dielectric used in reduced-diameter types of electric cables in sizes 3, 4, and 9. Special care should be exercised in handling the cables to avoid sharp bends and kinks that can damage the silicone rubber insulation on the old types that did not employ a nylon jacket over each insulated conductor.

Class T insulation is a silicone rubber treated glass tape, which is also used in reduced-diameter cables in sizes 14 through 800.

Propulsion generators and motors are usually insulated with class B insulating materials. Ship's service and emergency generators may have either class A, B, or H materials; however, the trend is away from class A. Auxiliary motors are usually class A, although the trend is toward class B and class H materials. Lighting transformers for 60-cycle service are class B insulated, and 400-cycle transformers are class H insulated. Miscellaneous coils for control purposes may be class A, B, or H, but the majority of such coils are class A insulated.

It is important to maintain operating temperature of electrical equipment within their designed values to avoid premature failure of insulation. Temperatures only slightly in excess of designed values may produce gradual deterioration, which, though not immediately apparent, shortens the life of the insulation. The highest temperature (hot-spot temperature) to which class O insulation may be subjected continuously with normal life expectancy (5 years) is 90° centigrade, class A insulation, 105° centigrade; class B insulation, 130° centigrade; and class H, 200° centigrade. No limit has been established for class C insulation.

The maximum allowable temperature rise and the design ambient temperature for electrical equipment are usually shown on the nameplate, on equipment drawings, and in the technical manual for the equipment. When information is not available from these sources, the maximum permissible temperature rises, shown in Chapter 9600, NavShips Technical Manual, shall be used as a guide for checking or testing windings of rotating electrical machinery.

In chapter 6 of this text; "Maintenance of Motors and Generators", additional coverage is given on insulation.

Insulation Resistance Measurements

The insulation resistance of shipboard electrical cable must be measured periodically with an insulation-resistance-measuring instrument (megger) to determine the condition of the cable.

Varying the position of the arm of R13 affects the static conduction, thus affecting vertical centering.

The arm of R23 is also picking off a portion of the sawtooth and applying it to the grid of V10. V10 shares the multivibrator cathode resistor R18 and is cut off during the same time that V7 is cut off. When the grid voltage of V10 rises enough to overcome its bias, V10 will conduct and will increase the voltage developed across R18. Let us now recall the normal multivibrator action of V6 and V7. Normally, when C2 discharges through R20 sufficiently, V7 will conduct and develop additional voltage across R18, causing V6 to cut off. The added voltage increase caused by V10 increases the bias on V6 and stops its conduction prior to the normal discharge of C2. This causes the plate voltage of V6 to rise, which allows V8 to conduct and discharge C4. The sweep is now terminated. Thus the sweep is started, developed, and terminated prior to the normal discharge of C2, and V6 is ready for the next MTP, which will come when the transmitter fires again.

Horizontal deflection is accomplished more easily. A potentiometer is connected between two potentials. As shown in figure 17-18, this potentiometer is R1 and is connected between B+ and ground. The arm is geared to the antenna mechanically so that, as the antenna scans from side to side, the arm varies this voltage between fixed limits. This developes a back-to-back sawtooth which is directly coupled to the grid of V1. Direct coupling is employed in this circuit because of the low frequencies involved. The frequency is the same as the scan rate of the antenna and would likely fall between 0.5 and 2 cycles per second.

V1 and V2 comprise a grounded-grid paraphase amplifier which functions in exactly the same manner as V4 and V5. Therefore, as the voltage at R1 rises and falls, push-pull action will be developed on the horizontal deflection plates of the indicator V3 and the vertical sweep will move from side to side with the scanning of the antenna.

Scope Presentation

When the antenna is rotated and the sweep moves away from the center position, B-scan distortion is introduced. This distortion can be best visualized by taking the wedge-shaped sector which the antenna is scanning, breaking it open at the apex, and pulling the sides outward until they are vertical. (See fig. 17-19.) The base, broken at O, shows the sector in the process of being drawn out. This illustrates the way the same sector will appear in a B-scan presentation.

Some lines have been drawn on the sector and we must observe what has happened to each one of them. Note that the point O has been stretched into the line O-O'. The line O-O' thus represents a single point located in space directly at, under, or over the antenna. All lines such as A-O, C-O, F-O, and B-O have become vertical. A homing problem is made simple by the fact that any target that can be caused to move to the bottom of the indicator will be on a collison course. Notice also the line C-G. This line indicates the path of a target passing to the left. Now notice that this line of the presentation is a sweeping curve to the

Figure 17-19. —B-scan distortion due to expanded base.

4133

Cable insulation measurements should be made often enough (if operating conditions permit) to ensure that power and lighting circuits will have an accurate measurement at least once every 3 months during the first year after installation, thereafter, measurements are taken only at overhaul periods or if damage to the cables is suspected. These conditions are detailed in the NavShips Technical Manual, Chapter 9600. More frequent measurements may be made if a comparison with similar earlier measurements indicates a significant decrease in insulation resistance. In addition, cognizant Bureau Directives or Instructions may require that more frequent cable insulation-resistance measurements be made on some circuits; for example, degaussing coil measurements are required weekly on some degaussing installations.

Factors that affect cable insulation resistance measurements are the length of the cable, type of the cable, temperature of the cable, and the equipment connected in the circuit. Each of these factors must be evaluated to reliably determine the condition of the cable from the measurements obtained.

Length of Cable

The insulation resistance of a length of cable is the resultant of a number of small individual leakage paths or resistances between the conductor and the cable sheath. These leakage paths are distributed along the cable. Hence, the longer the cable, the greater the number of leakage paths and the lower the insulation resistance. For example, if one leakage path exists in each foot of cable, there will be 10 such paths for current to flow between the conductor and the sheath in 10 feet of cable, and the total amount of current flowing in all of them would be 10 times as great as that which would flow if the cable were only 1 foot long. Therefore, to establish a common unit of comparison, cable-insulation resistance should be expressed in megohms (or ohms) per foot of length. This is determined by multiplying the measured insulation resistance of the cable by its total length in feet.

When measured insulation resistance is converted to insulation resistance per foot, the total length of cable to be used is equal to the length of the cable sheath for single conductor cable and for multiple conductor cable in which each conductor is used in one leg of a circuit. For example, in a TSGA cable with a cable sheath of 100 feet in which the three conductors are phases A, B, and C of a 3-phase power circuit, the total length of the cable is 100 feet, not 300 feet. The reason for this is that each conductor is measured separately. If this cable is connected, either in series or parallel, to a similar cable that has a sheath length of 400 feet, the total length is 500 feet. As another example, 200 feet of type MSCA-7 cable (7-conductor cable) connected to 200 feet of MSCA-24 cable (24-conductor cable) represents a total cable length of 400 feet.

Because degaussing cable is installed in the form of a loop and the conductors in the multiple conductor cable used are connected in series where the ends of the cable meet to form a single coil with as many turns as there are conductors in the cable, the total length of multiconductor degaussing cable is equal to the length of the cable sheath times the number of conductors. For example, the total length of a type MDGA-19 cable (19-conductor cable) with a cable sheath of 500 feet is 9500 feet (500 x 19 = 9500).

Type of Cable

Insulation resistance will vary considerably with the nature of the insulating materials used in construction of the cable. Therefore, it is possible to determine the condition of cable insulation by resistance measurements only when they are considered in relation to the typical characteristics of the particular type cable.

Figure 3-39 shows a resistance test record card to be used for power, lighting, and degaussing circuit cables. Parts A and B of figure 3-39 are the front and reverse sides of the resistance test record card, respectively.

The front of the card is filled in with the circuit designation, length, card number, and index. The vertical columns are filled in as measurements are taken. The date and measured resistance megs are listed (these are the actual megger readings). The ambient temperature assumed is listed as follows. The cable temperature shall be considered 104° F if the cable has been energized for four hours or more. If in a warm climate or a condition in which the entire cable is in a heated space and not in contact with the ship's hull (on hangers, not flush against hull), the temperature is considered to be at 70° F. If in a cold climate

or a condition in which most of the cable is in an unheated space or against the ship's hull in cold waters, the temperature is considered to be 40° F.

Having marked down the assumed temperature, the reverse side (part B of figure 3-39) of the card must be used for finding the resistance per foot (cable) megohms. To perhaps clarify the example shown on part B of figure 3-39, assume you had just completed a reading of 0.8 megohms on a degaussing circuit of 500 feet in length. On the lower right-hand side of part B is a listing of minimum allowable insulation resistance for cables (megohms/ft). Under the type of cable heading note point ①, point ②, and point ③ for DG cable at 104° F, 70° F, or 40° F, respectively. Assuming the 0.8 reading was taken just after shutdown, point ① would apply and the minimum megohms/ft would be 95 as shown in the block point ①. Having found the minimum, place a mark on the insulation resistance megohms per foot scale (center scale on left side of card) at the 95 position as now shown by ①. Drawing a straight line (shown dotted) from 0.8 on the measured insulation resistance scale across to the 500 ft mark on the length of cable scale, derives the insulation resistance in megohms per foot of the circuit just read at the point of intersection of the dotted line and the center scale (at approximately 400 megohms/ft as shown). Since the minimum was 95 megohm/ft and the circuit reads 400, it is in satisfactory condition.

If the same 0.8 reading had been obtained at a temperature of 40° F, however, the minimum allowable insulation resistance would be 5500 megohms/ft as shown by point ③. Thus the 400 megohms/ft reading would be below the minimum and would require investigation.

Temperature of Cable

If the results obtained by the assumed temperature method indicate unsatisfactory cable insulation then the actual temperature should be measured.

These measurements should be made by means of thermometers attached to the sheath or armor of the cable. The thermometers should be attached at several points along the cable run and the values should be averaged. To provide accurate temperature readings, the thermometer bulb should be in direct contact with the cable sheath or armor, and any paint should be scraped away. The thermometer should be held in place with pads of felt (or other heat insulating material) placed over the bulb and secured with friction tape. The number and location of thermometers should be such that a representative average temperatures (as shown in fig. 3-40) of the entire cable sheath is obtained. To find the minimum insulation megohms/ft for temperatures of 14° F to 212° F use the graph in figure 3-41. The upper curved line marked A on the graph is to be used for SGA, HF, DG, and SCA type cables, while the lower curved line marked B is for TTHFA and TTHFWA type cables. The graph extends to 212° F, however the maximum permissible operating temperature for nonflexing service cables is 185° F at the sheath. In using this graph the same values will be derived as those given on the Resistance Test record card NavShips 531 (10-63), revision. For example, the minimum for a SGA type cable at 104° F is 95 megohms/ft on either the card or graph. Using this graph in conjunction with average sheath temperature will provide a quick method of determining if cable insulation is satisfactory or in need of repair or replacement.

Equipment Connected in a Circuit

Initial measurements of insulation resistance of complete circuits should be made to avoid unnecessarily disconnecting apparatus with resultant loss of time, and labor, and possible damage to cables by handling. For

77.28

Figure 3-40.—Simplified electrical power circuits.

164

77.24

Figure 3-41.—Minimum insulation resistance values for nonflexing service cables.

this purpose, the circuits measured should be considered as beginning at the open switch (or circuit breaker) on the switchboard from which the test potential is supplied and extending through closed switches on distribution panels and boxes, fuse clips (fuses in place), etc., to its extremity, including line terminals of controllers, light fixtures, and switches. When measuring insulation resistance, always record the exact amount of equipment included in the circuit so that accurate comparisons can be made with similar past or future measurements.

Making Insulation Resistance Measurements

Measurements should be made on each individual leg of d-c circuits and each individual phase lead of 3-phase a-c circuits.

For lighting circuits, the legs or phase leads should include all panel wiring, terminals, connection boxes, fittings, fixtures, and outlets normally connected, but with lights turned off at their switches and with all plugs removed from the outlets (fig. 3-42). If local lighting switches are double pole, the insulation resistance of the local branch circuit will not be measured when the switch is open. In such cases, making an insulation test from one leg or phase lead to ground with the local switches closed will determine whether grounds exist on the circuits and fixtures.

For power circuits, the legs or phase leads should include panel wiring, terminals, connection boxes, fittings, and outlets (plugs removed), motor controller terminals, and other equipment that remains connected when the legs or phase leads are isolated by opening switches (or circuit breakers) at the switchboard, and by leaving motor controller contactors open (fig. 3-43).

For degaussing circuits, measurements should be taken at a degaussing coil connection box; the legs measured should include the coil cables, through boxes, and feeder cables. Disconnect the supply and control equipment by opening the circuit on the coil side of the control equipment. Measure the compass-compensating coil feeder cable with all control equipment disconnected. Additional information on tests of degaussing installations is obtained in NavShips Technical Manual, Chapter 9810, and in the degaussing folder furnished with each degaussing installation.

Measurements of these circuits (lighting, power, and degaussing circuits) should be made as follows:

1. Check to see that the cable armor is adequately grounded by measuring between the cable armor and the metal structure of the vessel (step 1, fig. 3-44); normally, grounding has been accomplished by means of cable straps. If a zero reading is not obtained, ground the cable armor.

2. Select one lead to be measured, and connect all the other leads in the cable together and ground them by means of temporary wires (step 2, fig. 3-44).

3. Measure the resistance of the lead being tested to ground (step 3, fig. 3-44). The test voltage should be applied until a constant reading is obtained. Hand-driven generator type instruments (meggers) should be cranked for at least 30 seconds to ensure a steady reading.

4. Repeat steps 2 and 3 as necessary to measure each leg or phase lead to ground (steps 4 and 5, fig. 3-44). When circuits contain permanently connected paths between legs or phases, such as transformers, indicator lights, control relays, etc., measurements need be made only between one lead and ground unless low readings requiring further tests are obtained.

77.25

Figure 3-42.—Measuring insulation resistance of a lighting circuit.

The readings obtained in accordance with the foregoing should be considered satisfactory if they are not less than 1 megohm for each leg or phase of a lighting or power circuit to ground, or less than 0.2 megohm from any leg, which includes the coil cables, the through boxes, and the feeder cables, of a degaussing circuit to ground. If the readings are lower than these minimum values, they should be considered satisfactory if they are not lower than previous measurements made under the same conditions (same cable with the same equipment connected and approximately the same average sheath temperature), provided

77.26

Figure 3-43.—Measuring insulation resistance of a power circuit.

77.27

Figure 3-44.—Measuring circuit insulation resistance.

the value of the previous measurements has been established as satisfactory by further investigation and satisfactory service operation.

Where the insulation resistance of a circuit is less than the minimum described above, the low resistance may be due to trouble localized in a segment of the circuit. To determine the cause, segregate the circuit into two or more parts by opening switches and circuit breakers, removing fuses, etc. at the feeder distribution panels and boxes, and measure the insulation resistance of each segment. One or more of the segments may indicate abnormally low resistance. The low values on these segments may be due to low insulation resistance at cable junctures or in equipment remaining connected to the segment. Inspect and correct any such faults by cleaning or corrective action as necessary. Then, measure the insulation resistance of the circuit and compare the values with readings obtained prior to the inspection and cleaning.

If the value is still low, disconnect all conductors in the questionable segment of the circuit and proceed as follows to ascertain the condition of the cable conductors:

1. Measure or closely estimate the average sheath temperature throughout the length of the cable being tested.

2. Measure the insulation resistance of each conductor in the cable.

3. Convert the measured insulation resistance to megohms per foot, and compare this value with the minimum satisfactory megohms per foot as shown (use Fig. 3-41) at the average cable sheath temperature.

4. If the megohms per foot of any conductor in the cable is less than the minimum satisfactory value indicated on the graph, an unsatisfactory condition is indicated and the cable section may require replacement or suitable corrective action.

5. If the megohm per foot of each conductor in the cable is higher than the minimum satisfactory value indicated on the graph, the circuit may be restored to the original condition by connecting the cable, replacing the fuses, and closing the switches, circuit breakers, etc. With the circuit as it was for the original measurements, measure it again. This reading should be recorded on the resistance test record card together with the notation as to which equipment remained connected.

If unsatisfactory readings are obtained, use the following procedures to determine and correct the cause of the low insulation resistance. The simplified circuit shown in figure 3-40 is used as an example.

The first step is to segregate the circuit into two parts by opening all the switches on panel 4-168-1. Additional measurements are made to determine whether the low insulation resistance is caused by that part between the switchboard and the distribution panel. The average sheath temperature, when measured by three thermometers (1, 2, and 3, fig. 3-40), is found to be 120° F, and the measured insulation resistance (for example) shows 160,000 ohms for phase A 140,000 ohms for phase B and 180,000 ohms for phase C.

The condition of the cable is determined by finding the insulation resistance per foot of the phase indicating the lowest resistance (phase B). This value is 43.4 megohms per foot (140,000 ohms x 310 ft = 43.4 megohms). The minimum safe insulation resistance of the upper curve (fig. 3-41) at 120° F is 35 megohms per foot. Because the lowest measured resistance of 43.4 megohms per foot is above the minimum safe value for type SGA cable, it appears that the condition of the cable is satisfactory.

Previous insulation resistance readings should always be compared to the present reading. Even though a circuit reads satisfactory (as the one in fig. 3-40) it should still be investigated if there is a noticeable decrease over previous readings. A circuit may read 30 megohms for several readings and then drop to 0.8 megohms and all of these readings still be within the minimum allowance. The 0.8 reading should be investigated and the cause of the decrease in insulation resistance eliminated as follows.

The next step is to further segregate the circuit by disconnecting the cable 3S-4P (4-168-1) from the distribution panel 4-168-1. An insulation resistance measurement is made on the cable, and this measurement gives a value of 1.2 megohms for the conductor with the lowest insulation resistance. This indicates that the distribution panel is probably contributing to the lowering of the resistance. An examination of the insulation around the bus bars in the panel discloses an accumulation of dust.

After the insulation of the panel is cleaned and the cable reconnected, another measurement is made, which shows a value of 1.5 megohms for the conductor with the lowest insulation resistance. This indicates that the condition has been corrected, and no further tests are necessary. The reading of 1.5 megohms is recorded on the Resistance Test Record Card (NavShips 531-1(10-63) for this circuit along with an entry giving the average sheath temperature and the equipment connected in the circuit.

It is recommended that a work log be maintained in which the date, insulation resistance, sheath temperature, equipment connected in the circuit, and other pertinent information (fig. 3-45) are recorded at the time the measurements are being made. This information will prove valuable when comparing measurements, and will provide the data required to be recorded on the resistance test record card.

CABLE FITTINGS

Stuffing Tubes

Periodic inspections should be made to determine the condition of stuffing tubes. Such inspections may be made in conjunction with other tests and inspections. Usually, visual inspection is sufficient to disclose the material condition of the fitting; however, watertightness of stuffing tubes is best determined by air tests. Loose seals occasionally develop due to one or more of several factors, such as loosening of the gland nuts, flowing of the intermediate or

soft packing in metal tubes, or "necking" of the cables, and by the loosening effect of alternate heating and cooling of the cables from energizing and deenergizing them.

There is only a remote chance of the stuffing tube gland nuts loosening or backing off after the compartment in which they are located has been painted, since the paint over the gland nuts will tend to keep them from turning. Loosening of the seal in metal stuffing tubes is more often caused by flow of the soft plastic packing into the interstices of the cable armor, or by depression or "necking" of the cable itself because of excessive packing pressure. Therefore, care must be taken when setting up gland nuts to avoid excessive packing pressure.

It is preferable that no stuffing-tube gland nuts be tightened except those that have obviously loosened or backed off, unless there is positive evidence of leakage through the stuffing tube. When gland nuts must be tightened, an additional turn of soft packing should be inserted if at all practicable.

Supports

The bolts and nuts that secure cable hangers, connection boxes, and wiring appliances to bulkheads and other supports may be loosened and lost because of vibration and gun fire. Periodic inspection should be made and all nuts and bolts securely tightened. Such an inspection should be made after firing, especially of those wireways in the vicinity of the guns.

TESTS AND INSPECTIONS

Certain periodic tests and inspections are necessary to ensure the satisfactory operation of shipboard electrical cable installations. The following schedule of tests and inspections should be used so far as practicable and may be supplemented by more frequent tests and inspections as unusual circumstances or conditions warrant.

1. Each watch: Use ground detector voltmeters or ground detector lamps at least once each watch to test for grounds on the circuits that are energized. Record the test and results in the electrical operation log.
2. After firing: Inspect wireways and securely tighten all nuts and bolts.
3. Weekly: Measure the insulation resistance of all degaussing cables with an insulation resistance measuring instrument.

11367

left. The fact that it is not on a collision course is apparent very early in a problem. Thus, homing is made quite simple. The presentation is not "maplike"; therefore, an operator must learn to interpret the presentation before he can use it to navigate efficiently. Actually, this does not take very long. All arcs around the antenna, such as A-F on the sector, tend to become straight lines. The greater the radius of an arc, the closer the arc approaches a straight line; therefore, distortion is less at longer distances and navigation at long ranges is much easier than it is at short ranges.

The distortion caused by the use of the B-scan is both good and bad, but with a little practice, the disadvantages can be greatly reduced.

C-SCAN

The C-scan type of presentation was developed primarily to be employed by the remote indicators used by pilots in earlier radar. However, the principle of the C-scan presentation is employed by many of the main indicators in aviation fire control equipment.

The basic purpose of the C-scan is to indicate the elevation and azimuth of a target relative to the attacking aircraft. (See fig. 17-20.) The relative altitude of the target aircraft is indicated by the position of the target relative to the horizontal centerline of the screen. The horizontal angle (azimuth) between the target aircraft and the heading of the attacking aircraft is represented by the displacement of the target from the vertical centerline of the indicator. Thus, the position of the target on the indicator would indicate both relative azimuth and elevation of the target aircraft.

Figure 17-20. —C-scan presentation.

Like B-scopes, C-scopes provide a rectangular display on their screens. To obtain a rectangular display on the screen of a C-scope, both horizontal and vertical sweep generators are used. Since the sweep frequencies are relatively low, potentiometers (like the azimuth sweep potentiometer of the B-scope) are generally used. These potentiometers are connected to the radar antenna.

When the antenna rotates horizontally, the scanning spot on the C-scope screen is deflected horizontally. When the antenna is tilted up or down, the scanning spot is deflected vertically. Echo signals applied to the control grid (or cathode) of the CRT during the sweep period causes the brightness (intensity-modulation) of portions of the horizontal trace to be increased. The position of a bright spot indicates the elevation and bearing of a target.

Targets at different ranges, but with the same bearing and elevation, appear as a single spot on a C-scope. Targets of this kind cannot be distinguished individually on the C-scope. For this reason, an indicator that presents range date is generally used in conjunction with a C-scope. Once the range of a particular target has been determined, a range gate pulse (rectangular pulse) is applied to the C-scope. This intensifies the electron beam only for the duration of the range gate pulse. Thus, only targets within the gated range will appear on the C-scope; all other signals are blanked out. In this way, the bearing and elevation of a particular target at a specified range can be determined.

A common application of the C-scan type of presentation is the display of steering error information. Usually this information is displayed as a steering circle and dot. The steering error information is in the form of voltages proportional to the difference between the actual flightpath of the attacking aircraft and the optimum flightpath of the attacking aircraft, required to score hits on the target. These voltages are applied to the deflection system of the CRT and thus the steering circle and dot are positioned on the screen relative to the heading of the attacking aircraft. Other voltages are also applied to the deflection system to form the steering circle.

A C-scan presentation can also be used to display information obtained from an infrared (IR) detector system.

1134

CHAPTER 4

SHIPBOARD LIGHTING

PRINCIPLES OF LIGHT

Light is radiant energy of those wavelengths that are capable of affecting the eye to produce vision. Radiant energy is emitted from various sources and varies in wavelength from 10^{-12} centimeters for cosmic rays to 10^{6} centimeters for radio rays. This range of wavelengths comprises the complete spectrum of electromagnetic waves, which travel through space at the velocity of approximately 186,000 miles per second.

The visible spectrum constitutes a narrow portion of the complete spectrum and includes red, orange, yellow, green, blue, and violet rays (figure 4-1). The range of wavelengths in the visible spectrum varies from 0.0008 millimeters for red rays to 0.0004 millimeters for violet rays. The spectrum extends beyond these limits into regions that are invisible to the eye. Radiation of greater wavelength beyond the red end is INFRARED and that of lesser wavelength beyond the violet end is ultraviolet.

PROPAGATION

The natural sources of light are the sun, stars, moon, and planets. The artificial sources include the electric-arc lamp, incandescent lamp, and fluorescent lamp. These sources of radiation (except the fluorescent lamp) are bodies at high temperatures, which produce vibration of the particles of matter. The radiated light travels in straight lines and behaves like wave motion in which the waves are transverse to the direction of propagation.

Light waves are of different wavelengths; different colors of light correspond to different frequencies of vibration; and electromagnetic waves of all wavelengths travel with the same velocity in free space, but with different velocities in different media. Hence, light waves obey the fundamental equation of wave motion,

$$f = \frac{V}{\lambda} = \frac{3 \times 10^{10}}{\lambda} \qquad (4\text{-}1)$$

where V is the velocity of light (3×10^{10} centimeters per second), f the frequency of vibration (number of waves passing a given point per second), and λ the wavelength in centimeters.

Light waves travel in straight lines in a homogeneous medium. When these rays, or lines, of propagation encounter a medium of greater or less density, some of the energy is absorbed and the remainder is either reflected by the boundary between two media or is refracted in passing obliquely from one medium into another, or through a medium of varying density. These phenomena (absorption, reflection, and refraction) usually occur when light impinges on most objects.

ABSORPTION

Absorption is the loss of energy that occurs when light rays strike an object and are dissipated in the form of heat. The amount of absorption depends on the nature of the object, the molecular construction, the wavelength or color of the incident light, and the angle at which the light strikes the object. All objects do not absorb light of different wavelengths in the same proportion. This phenomenon accounts for the characteristic color of objects illuminated by either sunlight or artificial white light.

REFLECTION

Reflection occurs when light rays strike an object and are deflected back from the surface in a different direction. When light falls on a

77.30

Figure 4-1.—Spectrum of electromagnetic radiation.

smooth, polished surface, it is reflected in a definite direction and is called REGULAR reflection (fig. 4-2). The light from the source to the polished surface is the INCIDENT RAY. The point at which the incident ray strikes the polished surface is the POINT OF INCIDENCE, P. The ray that leaves the point of incidence is the REFLECTED RAY. The line perpendicular to the polished surface at the point of incidence is the NORMAL TO THE SURFACE, N. The angle between the incident ray and the normal to the surface is the ANGLE OF INCIDENCE, i. The angle between the reflected ray and the normal to the surface is the ANGLE OF REFLECTION, r.

The incident ray, reflected ray, and normal to the point of incidence lie in the same plane,

77.31

Figure 4-2.—Reflection of a light ray.

and the angle of reflection is equal to the angle of incidence. This condition is true for both plane and curved mirror surfaces. The incident and reflected rays travel with the same velocity because they travel in the same medium.

When light falls on a rough, unpolished surface, it is reflected in all directions and is called diffuse (irregular) reflection. The only essential difference between regular and diffuse reflection is that diffuse reflection takes place from an infinite number of infinitesimal plane surfaces oriented in all directions.

REFRACTION

Refraction occurs when light rays pass obliquely from one medium to another of greater or less density and undergo an abrupt change in direction (figure 4-3). The incident ray enters the second medium at the POINT OF INCIDENCE, P. The ray that enters the second medium is the REFRACTED RAY. The line perpendicular to the surface at the point of incidence is the NORMAL TO THE SURFACE, NN'. The angle between the refracted ray and the normal to the surface in the second medium is the ANGLE OF REFRACTION, r'. The magnitude of the angle of refraction depends on the refracting medium and is not necessarily equal to the angle of incidence.

Both reflection and refraction occur in greater or less degrees at the boundary surfaces between most media. The boundary thus serves as reflecting surface for one ray and as a refracting surface for another. The normal to the surface, NN', and the incident and refracted rays lie in the same plane.

COLOR

As previously stated, light of different colors travels through space with the same velocity. Hence, in accordance with the fundamental equation of wave motion (equation 4-1), the frequencies are different for different colors and are inversely proportional to their wavelengths as,

$$\underline{f} = \frac{\underline{V}}{\lambda},$$

where $\underline{f}$ is the frequency, $\underline{V}$ the velocity, and λ the wavelength.

The impression of color depends on the frequency of the light that is reflected or transmitted to the eye. The primary colors of light

77.32

Figure 4-3.—Refraction of a light ray.

in the visible spectrum are red, green, and blue. Light of any one of these colors cannot be produced by combining light of any other colors. However, light of any other color than these three can be produced by combining, in the proper proportion, light of any two or all three of the primary colors.

All objects absorb a certain amount of the light that falls on them, but all objects do not absorb the same proportion of light of different wavelengths. If all objects absorbed light in the same proportion, they would appear to have the same color. An object must be observed under white light for it to appear in its true colors. White light contains (in the proper proportion) all three primary colors.

If an object absorbs all or nearly all of the white light that falls on it, the object appears black in color. If it absorbs all the green and blue portions of white light that falls on it, the object appears red in color because only the red light is reflected to the eye. In other words, only the reflected light is seen. Those components of the visible spectrum absorbed by the object are not seen.

An object appears in its true colors only when the light falling on it contains light of the wavelengths that the object reflects or transmits. Thus, the light falling on a red object must contain red light for it to appear red in color. A red object observed under a light that contains only green and blue rays will appear black in color because the object absorbs the green and blue rays and is capable of reflecting or transmitting only red rays (which are not present).

CANDLEPOWER

The luminous intensity, or light-producing power, of a given source of light is a measure of the ability of the source to project light in a certain specified direction. The unit of luminous intensity is the CANDLE, or CANDLEPOWER, I, which is approximately equal to the intensity of light emitted from a seven-eighths-inch sperm (standard) candle burning at the rate of 120 grains per hour. Thus, the candlepower of light is expressed in terms of the standard candle that is considered to emit light equally in all directions. However, this condition is a theoretical concept and does not actually exist, but is necessary to develop the quantities and units used in lighting computations.

FOOT-CANDLE

The intensity of radiation is the light energy radiated or absorbed per unit time per unit area. Light energy is a flow of light waves that always originate from some source, such as the sun, a candle, or an incandescent lamp. The unit of illumination is the FOOT-CANDLE, E, which is the illumination on a surface that is 1 foot distant everywhere from a source having a luminous intensity of 1 candlepower.

INVERSE SQUARE LAW

In figure 4-4 a source of light produces a light intensity of candlepower, I, in the direction of surfaces A, B, and C. The illuminated surfaces are perpendicular to the direction from the light source and at a distance in feet, d, from the source. The illumination in foot-candles, E, falling on surfaces A, B, and C is expressed as an application of the inverse square law as follows:

$$E = \frac{I}{d^2} \qquad (4\text{-}2)$$

For example, if I is 100 candlepower and d is 1 foot, the illumination on surface A will be

$$E = \frac{100}{1^2} = 100 \text{ foot-candles.}$$

19370

77.33

Figure 4-4.—Inverse square law of radiation.

If $\underline{d}$ is 2 feet, the illumination on surface B will be

$$\underline{E} = \frac{100}{2^2} = 25 \text{ foot-candles.}$$

If $\underline{d}$ is 3 feet, the illumination on surface C will be

$$\underline{E} = \frac{100}{3^2} = 11.1 \text{ foot-candles.}$$

This relation results from the fact that the total quantity of light in the cone of light is the same at all distances from the source; whereas, the surface over which it is spread increases as the square of the distance. Hence, the illumination, which is the quantity of light per unit of surface, is inversely proportional to the square of the distance from the source. At any given distance from the source, the illumination is directly proportional to the candlepower.

LUMEN

Illumination is also expressed in terms of the lumen, which is the unit of luminous flux, or quantity of light. A lumen is that quantity of light flux that must fall on a surface having an area of 1 square foot in order to produce on that surface an illumination of 1 foot-candle.

The number of lumens per square foot is always numerically equal to the illumination in foot-candles, $\underline{E}$. Thus, the illumination that is produced by a total flux on an area is

$$\underline{E} = \frac{\Phi}{\underline{A}}, \qquad (4\text{-}3)$$

where $\underline{E}$ is the illumination in foot-candles, Φ the total flux in lumens, and $\underline{A}$ the area in square feet. For example, 1 lumen of flux distributed over an area of 1 square foot will produce 1 foot-candle of illumination over that surface. Similarly, 10 lumens of flux distributed over an area of 5 square feet will produce 2 foot-candles of illumination over the surface. If the distribution of flux over the area is nonuniform, equation (4-3) gives the average value of illumination. In calculating the illumination produced by a lamp in any given direction, the value of the luminous intensity used in the equation must be the value that applies in the appropriate direction.

The candlepower measured around a light source in a horizontal plane is the HORIZONTAL CANDLEPOWER. The average candlepower in this plane is the MEAN HORIZONTAL CANDLEPOWER. The mean or average value of candlepower measured in all directions about a light source is the MEAN SPHERICAL CANDLEPOWER. Unless otherwise stated, the candlepower rating of a lamp is usually given in mean spherical candlepower.

The total light flux, Φ, produced by a light source having a mean spherical candlepower, $\underline{I_o}$, is

$$\Phi = 12.57\, \underline{I_o}, \qquad (4\text{-}4)$$

where 12.57 is the surface area of a sphere of one foot radius, (The area of a sphere is $4\pi\underline{r}^2$.)

For example, a light source of 100 candlepower (mean spherical) will produce 12.57 x 100 = 1257 lumens of light flux.

If this light source is considered at the center of a sphere of one foot radius, the illumination on each square foot of surface of the sphere will be $\underline{E} = \Phi/\underline{A} = 1257/12.57 = 100$ lumens per square foot. Similarly, the illumination in foot-candles will be $\underline{E} = \underline{I_o}/\underline{d}^2 = 100/1^2 = 100$ foot-candles.

COSINE LAW OF ILLUMINATION

To find the illumination on a flat surface when the light is inclined to the normal, as illustrated in figure 4-5, the inverse square law (equation 4-2) and the cosine law are applied. The cosine law states that the illumination of a surface that is not normal to the light rays will vary as the cosine of the angle of inclination (θ). Thus, the inverse

77.34

Figure 4-5.—Cosine law of incidence.

square law and the cosine law are combined and expressed as

$$\underline{E} = \frac{\underline{I}}{d^2} \cos \theta, \qquad (4\text{-}5)$$

where $\underline{E}$ is the illumination at point $\underline{P}$ in foot-candles, $\underline{I}$ the intensity of the light source in candlepower in the direction of $\underline{P}$, and $\underline{d}$ the distance in feet to P (figure 4-5).

For example, if I is 200 candlepower, d is 10 feet, and θ is 60°,

$$\underline{E} = \frac{200}{10^2} \cos 60° = 1 \text{ foot-candle.}$$

LIGHT SOURCES

The source of electric light used in naval vessel are the (1) incandescent, (2) fluorescent, and (3) glow lamps. The incandescent lamp is the most commonly used type; however, the fluorescent lamp is used to a great extent. A complete list of lamps used by the Navy is contained in the Fleet Oriented Consolidated Stock List (FOCSL) in Federal Item Identification Number Sequence; the (FOCSL) is carried aboard all ships. The list includes the electrical characteristics, physical dimensions, applications, ordering designation, and an outline of each Navy type lamp.

INCANDESCENT LAMPS

There are over 100 types of incandescent lamps used aboard ship. These types include lamps for general lighting, for many types of signaling, for instrument lighting and indicator lights, for battery-powered flashlights and hand lanterns, for illuminated gun sights, and for a variety of specialized applications.

Construction

The incandescent lamp consists of a tungsten or carbon filament supported by a glass stem. The glass stem is mounted in a suitable base that provides the necessary electrical connections to the filament. The filament is enclosed in a transparent, or translucent glass bulb from which the air has been evacuated. The passage of an electric current through the filament causes it to become incandescent and to emit light. The filament is operated either in a vacuum or a gas-filled bulb to prevent oxidation and consequent failure of the filament, which would occur in air.

All Navy type 115- or 120-volt lamps (up to and including the 50-watt size) are of the vacuum type, except MS (military standard) 15545-2; and all lamps above 50 watts are of the gas-filled type. The use of an inert gas, which is a mixture of argon and nitrogen gases, retards the oxidation of the filament and allows it to be operated at higher temperatures that result in higher efficiencies. Lamps under 50 watts are of the vacuum type because the effectiveness of the inert gas in increasing the luminous output is less pronounced in the lower wattage lamps.

The incandescent lamp is further subdivided into tungsten- and carbon-filament types. The tungsten-filament lamps comprise most of those listed in this group.

Rating

Incandescent lamps are rated in watts, amperes, volts, candlepower, or lumens, depending on their type. Generally, large lamps are rated in volts, watts, and lumens. Miniature lamps are rated in amperes for a given single voltage and in candlepower for a voltage-range rating.

Classification

Standard incandescent lamps are classified according to the (1) shape of bulb, (2) finish of bulb, and (3) type of base.

19372

The classification of lamps according to the SHAPE OF BULB with the corresponding letter designation is illustrated in figure 4-6. The designation letter, which denotes the shape of the bulb, is followed by a numeral that denotes the diameter of the bulb in eights of an inch. For example, if the lamp illustrated in figure 4-6 F, is designated PS-52, it is a lamp with a pear-shaped bulb and straight sides having a diameter of 52/8, or 6 1/2 inches.

The lamps commonly used for general lighting aboard ship are 115- or 120-volt, 50-, 100-, and 200-watt rough service types. These lamps (up to and including the 150-watt size) have standard-line shaped bulbs, and those of 200 watts and above have pear shaped bulbs. The other bulb shapes are designed for lamps that are used for special types of service.

Rough-service (RS) lamps have specially constructed filaments that are supported at several points to increase their ability to withstand vibration and shock.

The classification of lamps according to the finish of bulb are the clear (CL) and the inside frosted (IF).

The CLEAR lamp consists of a bulb that is made of unclouded or luminous glass, which exposes the filament to view. These lamps are used with reflecting equipment that completely conceals the lamps to avoid glare.

The INSIDE FROSTED lamp consists of a glass bulb that has the entire inside surface coated with a frosting, which conceals the filament and diffuses the light emitted from the lamp. These lamps can be used with or without reflecting equipment.

12.80

Figure 4-6.—Classification of lamps according to shape of bulbs.

The classification of lamps according to the type of base is illustrated in figure 4-7. The size of the base is indicated by name, including miniature, candelabra, and intermediate; the type of the base provided with the different sizes is also denoted by name, including screw, bayonet, prefocus, and bipin.

The miniature, candelabra, and intermediate types of bases (figure 4-7 A, B, and C) are used on small-size lamps for detail lighting.

The medium base (figure 4-7E), which is the most commonly used type, is used on lamps (up to and including 300 watts) for general lighting.

The admedium base (figure 4-7D) is slightly larger in diameter than the medium base and is used on some mercury lamps.

The mogul base (figure 4-7F) is used on lamps rated above 300 watts. The three-control mogul base is used on 3-way lamps.

The medium and mogul prefocused bases are used on lamps provided with concentrated filaments, such as those used for motion picture projection.

The medium bipin base is used on fluorescent lamps described subsequently in this chapter. This medium bipost base is used on lamps of 500, 750, 1000, 1250 and 1500 watts principally for indirect fixtures. This design allows better heat radiation than can be obtained with the mogul screw base.

The mogul bipost base is used on lamps of 500, 1000 and 1500 watts and above, including floodlights.

Characteristics

The average life of standard lamps for general lighting service when operated at rated voltage is 750 hours for some sizes and 1000 hours for others. Every incandescent lamp is designed for operation at a certain specified voltage. The light output, life, and electrical characteristics of a lamp are materially affected when it is operated at other than the design voltage. Operating a lamp at less than rated voltage will prolong the life of the lamp and decrease the light output. Conversely, operating a lamp at higher than rated voltage will shorten the life and increase the light output. The characteristic curves for gas-filled incandescent lamps (figure 4-8) show how the performance is affected by operating the lamp at other than the rated voltage. For example, if a 120-volt lamp is operated at 114 volts, the voltage impressed on the lamp is 114/120 x 100, or 95 percent of rated voltage. From the characteristic curves, the lumens emitted from the lamp will be reduced to about 84 percent. Hence, a 5 percent reduction in rated voltage results in a 16 percent reduction in light output. The characteristic curves for vacuum lamps are not exactly the same, but are very similar to those of the gas-filled lamps, and, for all practical purposes can be considered to indicate their performance.

It is apparent from the characteristic curves that lamps should be operated as closely as possible to their rated voltage. Low voltage seriously decreases illumination; whereas, high voltage increases illumination, but an excess voltage of 5 percent will reduce the life of the lamp about one-half.

FLUORESCENT LAMPS

Fluorescent lamps are used aboard ship for general illumination in offices, messing and berthing spaces, machinery spaces, hangar bays, and for detail illumination in plotting rooms, for panels, and for small switchboards.

Construction

The fluorescent lamp is an electric discharge lamp that consists of an elongated tubular bulb with an oxide-coated filament sealed in each end to comprise two electrodes (figure 4-9). The bulb contains a drop of mercury and a small amount of argon gas. The inside surface of the bulb is coated with a fluorescent phosphor. The lamp produces invisible, short-wave (ultraviolet) radiation by the discharge through the mercury vapor in the bulb. The phosphor absorbs the invisible radiant energy and reradiates it over a band or wavelengths that are sensitive to the eye.

SINGLE-UNIT LAMPS.—Detail illumination is required where the intensity of general illumination is not sufficient, such as at desks, work benches, chart boards, and in engineering spaces for examination of gages. The fixtures for detail illumination commonly use single fluorescent lamps. Figures 4-9A and B illustrate the wiring arrangement for these single units.

Because of greater cost and shorter life of 8-watt fluorescent lamps, as compared to 15-watt and 20-watt lamps, fixtures with 8-watt lamps are used only for detail illumination and

Figure 4-7.—Classifications of lamps according to type of base.

12.79

77.35

Figure 4-8.—Characteristic curves for gas-filled incandescent lamps.

general illumination within locations where space is restricted.

MULTIPLE-UNIT LAMP FIXTURES.—Fluorescent lamps are now used for the majority of both red and white lighting on naval ships. The Navy has standardized on three lamp sizes, 8 watts, 15 watts, and 20 watts. The use of fluorescent lamps of over 20 watts has been limited to special installations.

The primary reason for not using larger lamps is their inability to withstand high impact shock. The longer, higher rated lamps such as the 40 watt and 60 watt are normally provided with the same bipin base as the shorter 8, 15, or 20-watt standard lamps. The use of special lamps as shown in figure 4-10, provides adequate protection against shock (note the new base).

These special (60-watt) lamps are being used in the 180 watt fixture in hangar spaces, over workbenches in weapons repair shops, and to illuminate the dock basins on LSD (landing ship dock) type ships. Red lighting is accomplished by enclosing a fluorescent lamp in a red plastic tube within a lighting fixture. The circuit arrangement for the latter requirement is shown in figure 4-9C.

D-C OPERATION.—Although the fluorescent lamp is basically an a-c lamp, it can be operated on d-c with the proper auxiliary equipment. The current is controlled by an external resistance in series with the lamp (figure 4-9D). Since there is no voltage peak, starting is more difficult and thermal switch starters are required.

Because of the power lost in the resistance ballast box in the d-c system, the overall lumens per watt efficiency of the d-c system is about 60 percent of the a-c system. Also, lamps operated on d-c may provide as little as 80 percent of rated life.

Auxiliary Equipment

The fluorescent lamp, like all discharge light sources, requires special auxiliary control

Figure 4-9.—Fluorescent lamps with auxiliary equipment.

The circuitry is not discussed because the Aviation Electronics Technician will only on rare occasions be concerned with this type presentation.

PPI-SCAN

The term PPI may be interpreted to mean plan position indicator. The PPI-scan is another type of scan developed for the purpose of presenting range and bearing information. It may be considered as a modified type of B-scan in which the rectangular coordinates are replaced with polar coordinates, thus presenting a polar maplike presentation of the area searched. Electromagnetic deflection is employed where a PPI-scan presentation is used. (See fig. 17-21.) This type of presentation is suitable for radar bombing operations. (NOTE: The PPI-scan is free of the type of distortion produced by the B-scan.)

The antenna for the PPI-scan presentation is rotated uniformly about the vertical axis, thus, searching or covering an area in the horizontal plane. The beam radiated by the antenna is usually narrow in azimuth and broad in elevation to give great slant range covered during surface and air search. However, where this type of presentation is used, the antenna can rotate through 360° or scan a pie-shape sector ahead of the aircraft. The antenna may be caused to scan back and forth through a selected sector by use of controls available to the operator. The scanning rate is quite rapid; therefore, the area scanned is covered frequently and the observed targets are presented distinctly on the screen of the CRT.

The PPI-scan is developed by causing the sweep or trace on the screen to rotate in synchronism with the antenna about the center axis of the CRT. Thus, each sweep is an indication of the instantaneous position of the antenna in azimuth. The rotation of the sweep is accomplished by varying the amplitude of the current through the vertical and horizontal deflection coils of the deflection yoke. The radial sweep is the time base and the range of a target is measured from the center of the screen (or from the sweep's starting point if depressed center is used) outward along the trace or sweep. Most PPI-scans utilize range markers to calibrate the screen. This is done by the timing system which causes the trace to be intensified at specific intervals. Thus, equally spaced concentric circles or arcs are produced which calibrate the screen in multiples of 1, 5, 10, or 20 miles or any other markers that are available for selection.

When a target echo is received, the intensity of the sweep increases, indicating the position of the target. The target may be presented in some detail, giving an indication of its size and shape. The target's range and relative position may be read directly from the screen with the aid of the range markers and an azimuth scale around the screen of the CRT.

The indicators employed in airborne radar may vary considerably in construction, types of scans, and in operating principles. However, their operation may be reduced to one or more of the basic types of scans previously discussed.

RHI-SCAN

An RHI-scope is essentially a normal PPI laid on its side so that the antenna scans vertically instead of horizontally. Range is still shown radially, but the angle that was formerly the bearing angle becomes the elevation angle. The vertical plane in which the RHI scans can be rotated about a vertical axis, as the horizontal plane of a normal PPI can be tilted around a horizontal axis. In an RHI, targets in a vertical plane only are displayed. The RHI screen shows a side view of this plane (fig. 17-22), the horizontal axis showing the range in miles and the vertical axis showing directly the height of the target aircraft in feet, and not the elevation angle. Height instead of elevation angle is obtained by electronically combining the range with the sine of the elevation angle. The height scale must be increased or stretched if significant information is to be obtained, particularly for distant aircraft. Figure 17-22 shows a height scale which has been stretched so that 5 nautical miles (30,000 feet) is equivalent to about 20 nautical miles of range.

PPI-SCAN CIRCUITRY

Figure 17-23 shows a simplified block diagram of PPI-scope. In the case illustrated, the CRT has a fixed deflection yoke. The sawtooth sweep currents required to produce the rotating radial sweep line are obtained from the trapezoidal-voltage sweep generator, a rotary transformer (synchro resolver), and two push-pull amplifiers.

1135

77.237

Figure 4-10.—Types of bases on different size fluorescent lamps.

equipment for starting and stabilizing the lamp. This equipment consists of an iron-core choke coil, or ballast, and an automatic starting switch connected in series with the lamp filaments. The starter (starting switch) can be either a glow switch or a thermal switch. A resistor must be connected in series with the ballast in d-c circuits because the ballast alone does not offer sufficient resistance to maintain the arc current steady.

Each lamp must be provided with an individual ballast and starting switch, but the auxiliaries for two lamps are usually enclosed in a single container. The auxiliaries for fluorescent lighting fixtures listed in NavShip's 250-560-4, (Lighting on Naval Ships) are mounted inside the fixture above the reflector. The starting switches (starters) project through the reflector so that they can be replaced readily. The circuit diagram for the fixture appears on the ballast container.

Operation

Fluorescent lamps installed aboard ship are of the hot-cathode, preheat starting type. A fluorescent lamp equipped with a glow-switch starter is illustrated in figure 4-9A. The glow-switch starter is essentially a glow lamp containing neon or argon gas and two metallic electrodes. One electrode has a fixed contact, and the other electrode is a U-shaped, bimetal strip having a movable contact. These contacts are normally open.

When the circuit switch is closed there is practically no voltage drop across the ballast, and the voltage across the starter, S, is sufficient to produce a glow around the bimetallic strip in the glow lamp. The heat from the glow causes the bimetal strip to distort and touch the fixed electrode. This action shorts out the glow discharge and the bimetal strip starts to cool as the starting circuit of the fluorescent lamp is completed. The starting current flows through the lamp filament in each end of the fluorescent tube, causing the mercury to vaporize. Current does not flow across the lamp between the electrodes at this time because the path is short circuited by the starter and because the gas in the bulb is nonconducting when the electrodes are cold. The preheating of the fluorescent tube continues until the bimetal strip in the starter cools sufficiently to open the starting circuit.

When the starting circuit opens, the decrease of current in the ballast produces an induced voltage across the lamp electrodes. The magnitude of this voltage is sufficient to ionize the mercury vapor and start the lamp. The resulting glow discharge (arc) through the fluorescent lamp produces a large amount of ultraviolet radiation that impinges on the phosphor, causing it to fluoresce and emit a relatively bright light. During normal operation the voltage across the fluorescent lamp is not sufficient to produce a glow in the starter. Hence, the contacts remain open and the starter consumes no energy.

A fluorescent lamp equipped with a thermal-switch starter is illustrated in figure 3-9B. The thermal-switch starter consists of two normally closed metallic contacts and a series resistance contained in a cylindrical enclosure. One contact is fixed, and the movable contact is mounted on a bimetal strip.

When the circuit switch is closed the starting circuit of the fluorescent lamp is completed (through the series resistance, R) to allow the preheating current to flow through the electrodes. The current through the series resistance produces heat that causes the bimetal strip to bend and open the starting circuit. The accompanying induced voltage produced by the ballast starts the lamp. The normal operating current holds the thermal switch open.

The majority of thermal-switch starters use some energy during normal operation of the lamp. However, this switch ensures more positive starting by providing an adequate preheating period and a higher induced starting voltage.

Characteristics

The failure of a hot-cathode fluorescent lamp usually results from loss of electron-emissive material from the electrodes. This loss proceeds gradually throughout the life of the lamp and is accelerated by frequent starting. The rated average life of the lamp is based on normal burning periods of 3 to 4 hours. Blackening of the ends of the bulb progresses gradually throughout the life of the lamp.

The efficiency of the energy conversion of a fluorescent lamp is very sensitive to changes in temperature of the bulb. The maximum efficiency occurs in the range of 100° F to 120° F, which is the operating temperature that corresponds to an ambient room temperature range of 65° to 85° F. The efficiency decreases slowly as the temperature is increased above normal, but also decreases very rapidly as the temperature is decreased below normal. Hence, the fluorescent lamp is not satisfactory for locations in which it will be subjected to wide variations in temperature. The reduction in efficiency with low ambient room temperature can be minimized by operating the fluorescent lamp in a tubular glass enclosure so that the lamp will operate at more nearly the desired temperature.

Fluorescent lamps are relatively efficient compared with incandescent lamps. For example, a 40-watt fluorescent lamp produces 2400 lumens, or 60 lumens per watt. A 40-watt incandescent lamp produces approximately 400 lumens, or 10 lumens per watt. Thus the fluorescent lamp produces six times as much light per watt as does the comparable incandescent lamp.

Fluorescent lamps should be operated at voltage within ±10 percent of their rated voltage. If the lamps are operated at lower voltages, uncertain starting may result, and if operated at higher voltages, the ballast may overheat. Operation of the lamps at either lower or higher voltages results in decreased lamp life. The characteristic curves for hot-cathode fluorescent lamps (figure 4-11) show the effect of variations from rated voltage on the condition of lamp operation. Also, the performance of fluorescent lamps depends to a great extent on the characteristics of the ballast, which determines the power delivered to the lamp for a given line voltage.

When fluorescent lamps are operated on a-c circuits, the light output executes cyclic pulsations as the current passes through zero. This reduction in light output produces a flicker that is not usually noticeable at frequencies of 50 and 60 cycles, but may cause unpleasant stroboscopic effects when moving objects are viewed. The cyclic flicker can be minimized by combining two or three lamps in a fixture and operating the lamps on different phases of a 3-phase system. Where only single-phase circuits are available, leading current is supplied to one lamp and lagging current to another so that the light pulsations compensate each other.

The fluorescent lamp is inherently a high power-factor device, but the ballast required to stabilize the arc is a low power-factor device. The voltage drop across the ballast is usually equal to the drop across the arc, and the resulting power factor for a single-lamp circuit with ballast is about 50 percent. The low power factor can be corrected in a single lamp ballast circuit by a capacitor shunted across the line. This correction is accomplished in a two-lamp circuit by means of a "tulamp" auxiliary that connects a capacitor in series with one of the lamps to displace the lamp currents, and, at the sime time, to remove the unpleasant stroboscopic effects when moving objects come into view.

GLOW LAMPS

Glow lamps are electric discharge light sources, which are used as indicator or pilot lights for various instruments and on control panels. These lamps have relatively low light output, and thus are used to indicate when circuits are energized or to indicate the operation of electrical equipment installed in remote locations.

Construction

The glow lamp consists of two closely spaced metallic electrodes sealed in a glass bulb that contains an inert gas. The color of the light emitted by the lamp depends on the gas. Neon gas produces an orange-red light, and argon gas

77.37

Figure 4-11.—Characteristic curves for hot-cathode fluorescent lamps.

produces a blue light. The lamp must be operated in series with a current-limiting device to stabilize the discharge. This current-limiting device consists of a high resistance that is usually contained in the lamp base.

Characteristics

The glow lamp produces light only when the voltage exceeds a certain striking voltage. As the voltage is decreased somewhat below this value, the glow suddenly vanishes. When the lamp is operated on alternating current, light is produced only during a portion of each half cycle, and both electrodes are alternately surrounded with a glow. When the lamp is operated on direct current, light is produced continuously, and only the negative electrode is surrounded with a glow. This characteristic makes it possible to use the glow lamp as an indicator of alternating current and direct current. It has the advantages of small size, ruggedness, long life, negligible current consumption, and can be operated on standard lighting circuits.

LIGHTING FIXTURES

A lighting fixture, or unit, is a complete illuminating device that directs, diffuses, or modifies the light from a source to obtain more economical, effective, and safe use of the light. A lighting fixture usually consists of a lamp, globe, reflector, refractor (baffle), housing, and support that is integral with the housing or any combination of these parts (fig. 4-12A). A globe alters the characteristics of the light emitted by the lamp. A clear glass globe (fig. 4-12B) absorbs a small percentage of the light without appreciably changing the distribution of the light. A diffusing glass globe absorbs a little more light and tends to smooth out variations in the spherical distribution of the light; whereas, a colored-glass or plastic globe absorbs a high percentage of the light emitted by the lamp. A baffle conceals the lamp and reduces glare. A reflector intercepts the light traveling in a direction in which it is not needed and reflects it in a direction in which it will be more useful.

CLASSIFICATION

Lighting fixtures are designated according to the type of enclosure provided, as watertight, nonwatertight, pressure-proof or explosion-proof. They are classified according to use as (1) regular permanent fixtures, (2) regular permanent red-light fixtures, (3) regular portable fixtures, (4) miscellaneous fixtures, (5) navigational lights, and (6) lights for night-flight operations.

REGULAR PERMANENT FIXTURES (incandescent, figs. 4-12A and B, fluorescent fig. 4-12C) are permanently installed to provide general illumination and such detail illumination as may be required in specific locations. General illumination is based on the foot-candle intensity required for the performance of normal routine duties. See the manual, Lighting on Naval Ships, NavShips 250-560-4. Detail illumination is provided where the general illumination is inadequate for the performance of specific tasks. Sources include berth fixtures, desk lamps, and plotting lamps.

REGULAR PERMANENT RED LIGHT FIXTURES (incandescent or fluorescent) are permanently installed to provide low-level, red illumination in berthing areas, in access routes to topside battle and watch stations, and in special compartments and stations. The incandescent fixtures are equipped with steam-tight inside-acid-etched red globes.

REGULAR PORTABLE FIXTURES (incandescent) are provided for lighting applications that cannot be served by permanently installed fixtures. These units are energized by means of portable cables that are plugged into outlets in the ship's service wiring system and include bedside lights, desk lights, and flood lights.

MISCELLANEOUS FIXTURES (incandescent or fluorescent) are provided for detail and special lighting applications that cannot be served by regular permanent or regular portable lighting fixtures. These fixtures include boom lights, crane lights, gangway lights, portable flood lanterns, hand lanterns, and flashlights.

NAVIGATIONAL LIGHTS (incandescent) include all external lights (running, signal, and anchor), except searchlights, which are used for navigational and signaling purposes between ships, and for communications when underway or at anchor.

LIGHTS FOR NIGHT-FLIGHT OPERATIONS are used to assist pilots (at night) when taking off and landing. These lights also provide visual aid to pilots for locating and identifying the parent aircraft carrier.

77.38

Figure 4-12.—Lighting fixtures.

11382

INTENSITY DEPRECIATION CALCULATIONS

Interior lighting should provide and maintain a sufficient amount of light to supply the desired value of illumination. This condition is partly accomplished by properly designed lighting fixtures so located as to produce reasonably uniform illumination without glare; thereafter, cleanliness of equipment and compensation for depreciation of illumination are important.

The direct fixture consists of a reflecting surface, above the light source, that redirects downward practically all (90 to 100 percent) of the light from the bare lamp.

The SEMIDIRECT fixture has a metal reflector that is open at the bottom and equipped with louvers to conceal the lamps and reduce glare. The unit directs a large portion (60 to 90 percent) of the light downward to the working surface.

The SEMI-INDIRECT fixture consists of a translucent enclosure that is open at the top. The unit transmits some of the light directly to the working surface through the translucent enclosure, and the remainder (60 to 90 percent) of the light is directed to the overhead, which, in turn, reflects it indirectly to the working area.

The INDIRECT fixture is provided with a metal enclosure that is open at the top. The unit transmits 90 to 100 percent of the light to the overhead, which, in turn, reflects the light indirectly to the working area. The majority of lighting installations in naval vessels are of the direct and semidirect types.

Candlepower Distribution Graphs

As previously stated, the candlepower distribution of lamps and fixtures is not uniform. Thus, in calculating the illumination that they produce in any given direction, it is necessary to use the candlepower in that direction. Candlepower distribution curves that indicate the candlepower of the source in all directions are used for this purpose. These distribution curves or graphs are furnished by manufacturers of lighting equipment and are supplied for various types of lamps alone or for lamps when used in conjunction with lighting fixtures.

The distribution graphs of three typical Navy lighting fixtures are illustrated in figure 4-13. A distribution graph is obtained by measuring the candlepower (with a photometer) directly downward from the source. This value is indicated on the vertical to a given scale of a circular chart and represents the candlepower directly below the light (0°). Similarly, the candlepowers around the light are measured at angles of 10° above the vertical. These values are indicated on the chart and represent the candlepowers to scale at the angles above the vertical of 10°, 20°, 30°, and so on around the light. These points are joined by a continuous line that represents the complete distribution graph of the light source. Thus, the candlepower in any direction is the length of the line drawn in that direction from the source to the curve.

The principal methods used in calculating illumination are the (1) point-by-point and (2) lumen methods.

Point-by-Point Method

The illumination at any point on a surface can be calculated by using equation (4-5) in conjunction with the candlepower distribution curve of the specific lamp or lighting fixture. When several fixtures contribute illumination to a given point, the candlepower distribution must be calculated for each fixture, and the actual illumination at any point on a surface will be the sum of the foot-candles contributed by all the fixtures, plus the light that is reflected to the point by the surrounding surfaces.

For example, find the illumination produced on a horizontal surface by two 50-watt, wide-angle, distributing types of overhead fixtures if one unit is located 4 feet away in a direction 30° from the vertical and the other is 7 feet away in a direction 60° from the vertical. The first fixture delivers approximately 90 candlepower in the direction 30° from the vertical (curve B of figure 4-13). The illumination produced by the first fixture from equation (4-5) is

$$E_1 = \frac{90}{4^2} (\cos 30° = 0.866) = 4.86 \text{ foot-candles.}$$

Similarly, the second fixture delivers approximately 60 candlepower in the direction 60° from the vertical (curve B of figure 4-13), and the illumination produced is

$$E_2 = \frac{60}{7^2} (\cos 60° = 0.5) = 0.612 \text{ foot-candles.}$$

77.39

Figure 4-13.—Candlepower distribution graphs.

Then the illumination contributed by both lamps is

$$\underline{E} = 4.86 + 0.612 = 5.47 \text{ foot-candles.}$$

The point-by-point method is useful in many shipboard lighting calculations for computing the illumination in spaces that are very irregular in shape and where there are many overhead obstructions. Also, this method is readily applicable for calculating detail lighting where only a single light source is required.

Lumen Method

The lumen method gives the average illumination on the horizontal for any system of general lighting where the light sources are spaced

CSC 1384

sufficiently close to each other to produce approximately uniform illumination.

This method is more practicable for calculating the illumination in larger spaces that require a greater number of lighting fixtures. In this method, a maintenance factor and a coefficient factor must be considered because the lumens required of the light source are calculated from the useful lumens desired on the working surface.

The MAINTENANCE FACTOR is applied to compensate for the difference in the average illumination obtained initially (when the lamps and units are new) and the resulting average illumination maintained in service. A maintenance factor of 70 percent shall be applied in computations, unless otherwise indicated on the standard plan of the lighting fixture being installed.

The UTILIZATION FACTOR, or coefficient of utilization, is the overall efficiency of the lighting installation and is the ratio of the useful lumens that reach the working area to the total lumens produced by the lighting fixture. Utilization factor tables for some specified types of lighting fixtures are available in the manual Lighting on Naval Ships, NavShips 250-560-4, or in the applicable manufacturer's instruction books.

NAVIGATIONAL LIGHTS

The navigational lights installed on naval vessels must be in accordance with Regulations for Preventing Collisions at Sea (Public Law 178, 82nd Congress, chapter 495) or as allowed by an existing waiver or a waiver to be issued covering the vessel being built. These lights consist of (1) running lights, (2) signal lights, and (3) anchor lights.

RUNNING LIGHTS

The running lights are similar to those used on merchant ships and include (1) masthead light, (2) range light, (3) port side light, (4) starboard side light, (5) stern light (white), and (5) upper and lower towing lights, some of which are illustrated in figure 4-14.

The MASTHEAD LIGHT (white) for ships is a 20-point (225°) light (fig. 4-14A) located on the foremast or in the forward part of the vessel. It is a spraytight fixture provided with a 50-watt, 2-filament lamp and equipped with an external shield to show an unbroken light over an arc of the horizon of 20 points—that is, from right ahead to 2 points abaft the beam on either side.

The RANGE LIGHT (white) for ships is also a 20-point (225°) light located on the mainmast or the fore part of the vessel, but at least 15 feet higher and 15 feet aft of the masthead light.

The PORT and STARBOARD SIDE LIGHTS for ships are 10-point, 112 1/2° lights (fig. 4-14B) located on the respective sides of the vessel, showing red to port and green to starboard. The fixtures are spraytight, each provided with a 100-watt, 2-filament lamp and equipped with an external shield arranged to throw the light from right ahead to 2 points abaft the beam on the respective sides.

The STERN LIGHT (white) for ships is a 12-point (135°) light (fig. 4-14C) located on the stern of the vessel. It is a watertight fixture provided with a 50-watt, 2-filament lamp and equipped with an external shield to show an unbroken light over an arc of the horizon of 12 points of the compass—that is, from dead astern to 6 points on each side of the ship.

The UPPER and LOWER TOWING LIGHTS (white) for ships not normally engaged in towing operations are 20-point (225°) lights similar to the previously described masthead and range lights. They are portable fixtures, each equipped with a type THOF-3 cable and plug connector for energizing the lights from the nearest lighting receptacle connector. When these lights are used, they are located vertically (6 feet apart) in the fore part of the vessel.

SIGNAL LIGHTS

The signal lights installed on combatant ships usually include (1) aircraft warning lights, (2) blinker lights, (3) breakdown and man overboard lights, (4) steering light, (5) stern light (blue), (6) wake light, and (7) speed lights (fig. 4-15). The supply switches for these lights located on the signal and anchor light supply and control panel (in the pilothouse) are individual ON-OFF rotary snap switches.

The AIRCRAFT WARNING LIGHTS (red) for ships are 32-point (360°) lights (fig. 4-15A) installed at the truck of each mast that extends more than 25 feet above the highest point in the superstructure. Two aircraft warning lights are installed if the light cannot be located so that it is visible from any location throughout 360° of azimuth. However, a separate aircraft warning light is not required if a 32-point red light is

77.41

Figure 4-14.—Running lights.

installed at the truck of a mast for another purpose. The fixtures are spraytight and equipped with multiple sockets provided with 15-watt, 1-filament lamps (fig. 4-15A). Upon experiencing a single lamp failure, all of the lamps in the cluster should be replaced.

The BLINKER LIGHTS (white) for ships are 32-point (360°) lights (fig. 4-15B) located, one port and one starboard, outboard on the signal yardarm. The fixtures are spraytight, each provided with 15-watt, 1-filament lamps and fitted with a screen at the base to prevent glare or reflection that may interfere with the navigation of the ship. These lights are operated from signal keys located on each side of the signal bridge.

Older blinker units (fig. 4-15B) have a cluster of six 15-watt lamps in a single multiple-lamp socket, similarly arranged as in the warning light (fig. 4-15A). Later units (not illustrated) are covered by NavShips drawing 815-F-1197117-B. These later units have two clusters of six lamps. Cluster No. 1 may be used singly for normal use. Cluster No. 2 may be added by switching to increase brilliance for communication at greater distance. Cluster No. 2 may be selected alone when No. 1 fails.

113861

77.44

Figure 4-15.—Signal lights.

The BREAKDOWN and MAN-OVERBOARD LIGHTS (red) for ships are 32-point (360°) lights located 12 feet apart (vertically) and mounted on brackets that extend aft of, and to starboard of the mast or structure. This arrangement permits visibility, as far as practicable, throughout 360° of azimuth. The fixtures are spraytight and equipped with 15-watt, 1-filament lamps. When these lights are used as a man-overboard signal, they are pulsed by a

ANTENNA POINTING DIRECTLY AHEAD (0°)

ANTENNA POINTING TO 90°

ANTENNA POINTING TO 270°

Figure 17-21.—PPI presentation.

1136

rotary snapswitch (fitted with a crank handle) on the signal and anchor light supply and control panel. These lights are mounted and operated in conjunction with the ships task lights discussed later in this chapter.

The STEERING LIGHT (white) for ships (fig. 4-15C) is installed on the jack staff or other spar or structure and must be visible to the helmsman in the pilothouse. The light is installed on the centerline if the pilothouse is on the centerline. If the pilot house is not on the centerline, a vertical plane through the light and helmsman's station in the pilothouse must be parallel to the keel line. The fixture is spraytight and includes a disk screen having a 3/64" x 1" slot (opening) through which light is emitted from a 2-candlepower lamp. A suitable bracket is provided for mounting the light on a jack staff (one-half inch in diameter).

The STERN LIGHT (blue) for ships is a 12-point (135°) light similar to the previously described white stern light (fig. 4-14C). The light is installed near the stern on ships that are engaged in convoy operations and mounted to show an unbroken arc of light from dead astern to six points on each side of the ship.

The WAKE LIGHT (white) for ships is installed on the flagstaff or after part of the ship to illuminate the wake, and mounted so that no part of the ship is illuminated. The fixture is spray tight and of tubular construction. One end of the fixture is fitted with an internal screen, having a 1-inch-diameter hole provided with a lens (2 5/16" diameter x 3/8" thick) through which light is emitted from a 100-watt, 2-filament lamp. A suitable mounting bracket is included for adjusting the position of the light. Thus, the wake light puts a "target" in the ship's wake.

The SPEED LIGHTS for ships are combination red (top) and white (bottom), 32-point (360°) lights (fig. 4-15D). They are located at the truck (top) of the mainmast, except when the height of the foremast is such as to interfere with their visibility; in this case, they are located at the truck of the foremast. Two speed lights are installed if their light cannot be located so that they are visible throughout 360° of azimuth.

Speed lights are provided to indicate (by means of a coded signal) the speed of the vessel to ships in formation. In other words, they indicate the order being transmitted over the engine order system. The white light indicates ahead speeds, and the red light indicates stopping and backing. The fixture is spraytight and equipped with a multiple socket (fig. 4-15E) provided with nine 15-watt, 1-filament lamps. Six lamps are used in the top of the socket for the red light and three in the bottom for the white light, each light is energized from separate circuits.

The controller for the speed lights is located in the pilot house.

The speed light controller is energized through the supply switch on the signal and anchor light controls and supply panel. Automatic operation of the speed light system is accomplished by placing the circuit control switch in the MOTOR PULSE position and the signal (speed) selector switch to the desired position. This action establishes connections to the motor-driven pulsator to provide the following signals.

Signal Selector Switch Dial Markings	Pulsations
Standard speed ahead	Steady white light (motor off)
One-third speed ahead	One white flash in 6 seconds
Two-thirds speed ahead	Two white flashes in 6 seconds
Full speed ahead	Four white flashes in 6 seconds
Flank speed ahead	Five white flashes in 6 seconds
Hand pulse key ahead	Manually controlled (code same as above)
Stop	Steady red light (motor off)
Slow speed back	One red flash in 6 seconds
Full speed back	Two red flashes in 6 seconds
Hand pulse key back	Manually controlled (code same as above)

If the pulsator unit should fail, manual operation of the speed light system is accomplished by placing the circuit control switch in the Hand Pulse (Red or White) position. This action connects the Hand Pulse key in the speed light circuit so that the signals can be transmitted manually, using the same code as that for the automatic pulsator. A schematic wiring diagram of the controller components is illustrated in figure 4-16.

The speed light is used as an aircraft warning light to provide a steady red light by placing the signal selector switch in the stop position and the circuit control switch in the AIRCRAFT WARNING position.

77.45

Figure 4-16.—Speed light control, schematic diagram.

21389

The d-c speed light system is identical to the a-c system except that a resistance unit replaces the transformer to reduce the voltage applied to the dial lights, and a shunt motor replaces the a-c motor in the pulsator unit.

CHANGES TO "INTERNATIONAL REGULATIONS FOR PREVENTING COLLISIONS AT SEA"

The following regulation changes became effective on 1 September 1965. Type Commanders issued the necessary instructions or took appropriate action to ensure that all ships complied with these changes.

Rule 3(a) was amended to require the upper and lower lights in the Towing Lights array to be equidistant from and not less than 6 feet above or below the middle light.

Rule 4(c) was amended to require vessels engaged in replenishment-at-sea or in the launching and recovery of aircraft to display the lights commonly referred to by the Navy as Ship's Task Lights.

Rule 4(d)(i) A vessel engaged in minesweeping operations shall carry at the fore truck a green light, and at the end or ends of the fore yard on the side or sides on which danger exists, another such light or lights. These lights shall be carried in addition to the lights prescribed in Rule 2(a)(i) or Rule 7(a)(i), as appropriate, and shall be of such a character as to be visible all round the horizon at a distance of at least 2 miles. By day she shall carry black balls, not less than 2 feet in diameter, in the same position as the green light.

Rule 4(d)(ii) The showing of these lights or balls indicates that it is dangerous for other vessels to approach closer than 3,000 feet astern of the minesweeper or 1,500 feet on the side or sides on which danger exists.

Rule 11(d) was amended to require a vessel 150 feet or over in length to have the forward anchor light located near the stem of the vessel in lieu of in the forepart of the vessel.

ANCHOR LIGHTS

The forward and after anchor lights (white) for ships are 32-point (360°) lights. The forward anchor light is located near the stem of the vessel, and the after anchor light is at the top of the flagstaff. The fixtures are splashproof, each provided with a 50-watt, 1-filament lamp. The anchor lights are energized through individual on-off rotary snap switches on the signal and anchor light supply and control panel in the pilothouse.

SHIP'S TASK LIGHT

This array consists of three 32-point (360°) lights, stepped out 45 degrees aft and to starboard of the mast, in a vertical line one over the other so that the upper and lower lights shall be the same distance from, and not less than six feet above or below, the middle light and be visible all around the horizon at a distance of at least 2 miles. The upper and lower lights of this array shall be red, utilizing the presently installed Man-overboard and Breakdown Lights, relocated as necessary. The center light shall be a white light.

These lights shall be connected to the Navigational Light Supply and Control (no telltale) Panel as follows:

(1) So that the two red lights may be burned steadily to indicate the ship is Not Under Command

(2) So that the two red lights may be flashed by rotating the switch (crank type) handle, to indicate a man-overboard condition exists

(3) So that the three lights will burn simultaneously to indicate the ship is either launching or recovering aircraft or engaged in replenishment-at-sea operations and by the nature of its work is unable to get out of the way of approaching vessels. The switch for this application shall be labeled "Ship's Task Lights".

SUBMARINE IDENTIFICATION LIGHT

This light is displayed solely for identifying a craft on the surface as a submarine. Its display does not change any of the Rules of the Road

11390

nor confer any privilege on the ship showing it. The light is an amber rotating light producing 90 flashes per minute, visible all around the horizon, and located approximately six feet above the masthead light.

TESTING NAVIGATIONAL LIGHTS

All shipboard navigational lights are tested daily while at sea. The test is usually made one hour prior to sunset by the Electrician's Mate with the day's duty. Weekly test of navigational lights should include the operational test of the telltale panel.

SUPPLY, CONTROL, AND TELLTALE PANEL

The supply control and telltale panel for the running lights is a nonwatertight, sheet metal cabinet designed for bulkhead mounting (fig. 4-17).

This panel is provided to aid a ship in keeping her running lights lit as prescribed by the rules for preventing collisions at sea. It is installed in or near the pilot house and gives an alarm when one of the running lights is out or has had a failure of its primary filament and is operating on its secondary filament.

Failure of the primary filament, or its circuit, of any one of the following lights: masthead, stern, range, and side lights, deenergizes a relay. This relay effects a transfer of power to the secondary filament of the affected light, sounds a buzzer, lights an indicator light and moves an annunciator target to read, OUT (reads RESET when deenergized). The buzzer may be silenced during repairs for storing the primary filament by turning the handle of the reset switch 90° (to the horizontal position), however the indicator lamp of the affected light stays lit until the repair has been completed and the reset switch is turned back to the normal (RESET) position. Certain ships have permanent towing lights installed and connected to control switches on the telltale panel. The towing light switches are manual. When failure of the primary filament occurs in towing lights connected to this panel the switch must be manually turned to the position marked "SEC", to energize the secondary filament.

Sequence of Operations

The operations of the supply control and telltale panel are easily seen by following the schematic diagram in figure 4-18. For simplification this schematic shows only one of the five running lights, the operation is the same for all five.

77.42

Figure 4-17.—Supply, control, and telltale panel.

When the primary filament of a running light is lighted, relay contacts (X, Y and Z) are open, indicator lamps, annunciator and buzzer are not energized, reset switch must be kept pointing in the (vertical) "RESET" (marked position) under normal condition or buzzer will not be energized when a failure occurs.

If the primary filament circuit is opened, as when the filament burns out, the relay is de-energized closing contacts (X and Y), secondary filament is lighted, indicator lamps are lighted, annunciator target moves to "OUT" position (closing contact Z) and the buzzer sounds.

11391
Sect I

77.43A

Figure 4-18.—Running light control schematic diagram.

When the "RESET" switch handle is turned to the horizontal (unmarked) position, the buzzer is silenced but the indicator lamps remain lighted and the annunciator target is still OUT.

When the defective lamp is replaced, (or fault in primary circuit is corrected) the relay coil is energized and relay contacts (X and Y) are opened, annunciator coil is deenergized (opening contact Z) and target indicates RESET, secondary filament is deenergized, indicator lamps remain lighted.

Reset switch is returned to RESET (vertical) position, indicator lamps go out and entire unit is again in normal condition.

Dimmer Control Panel

A dimmer control panel connected as shown in figure 4-18 is provided for dimming the running lights when directed. This panel provides but one position of dimming. In the dim position the visibility of the range, masthead, side lights, and stern light is reduced to about 4000 yards. The sequence of operation of the telltale panel is the same whether the running lights are in the light or dimmed condition.

DIVERSIFIED LIGHTING EQUIPMENT

Light traps and special lights also serve useful purposes aboard ship, which equipment the EM must repair and maintain. Visibility in all directions must be restricted with most of this equipment where the EM must take into account the lighting as affected by glare and background illumination.

NIGHT-FLIGHT OPERATION LIGHTS

Night-flight operation lights are installed on aircraft carriers to assist pilots during takeoff and landing at night. They also provide visual aid to pilots for locating and identifying the parent carrier, and for rendezvousing in the vicinity of the carrier. These lights are of a confidential nature and are therefore not listed in this training course.

DARKEN SHIP EQUIPMENT

Darkened ship is a security condition designed to prevent the exposure of light, which

could reveal the location of the vessel. Darkened-ship condition is achieved by means of (1) light traps that prevent the escape of light from illuminated spaces or (2) door switches that automatically disconnect the lights when the doors are opened.

Light Trap

A light trap is an arrangement of screens placed inside access doors or hatches to prevent the escape of direct or reflected light from within (fig. 4-19). The inside surfaces of the screens are painted flat black so that they will reflect a minimum of light falling on them. Light traps that are used to prevent the escape of white light should have at least two black, light-absorbing surfaces interposed between the light source and the outboard openings. Light traps are preferred to door switches in locations where (1) egress and ingress are frequent; (2) interruption of light would cause work stoppage in large areas; (3) light might be exposed from a series of hatches, one above the other on successive deck levels; and (4) many small compartments and passages are joined by numerous inside and outside doors that would complicate a door-switch installation.

Door-Switch

A door switch is mounted on the break side of a door jamb (inside the compartment) and operated by a stud welded to the door. When the door is opened, the switch is automatically opened at the same time.

Door switches are connected in a variety of ways to suit the arrangement of the compartment concerned. In a single compartment where there are several doors or hatches, door switches are connected in series so that when any one door or hatch is opened, all the lights in the compartment will be extinguished. When an inner compartment is located so that its light is visible from the deck when the doors to both the inner and outer compartments are open, the lights in the inner compartment are usually controlled by the door switch of the outer compartment. However, if this arrangement results in an excessive number of light interruptions in the inner compartment, a separate door switch connected in parallel with the outer door switch should be provided on the inner door to control the lights in the inner compartment.

77.46

Figure 4-19.—Light trap.

Thus, the lights in the inner compartment will be extinguished only when the inner and outer doors are open.

All door switch installations are provided with lock-in devices or short-circuiting switches to change the settings of the door switches, as required from lighted ship to darkened ship and vice versa. Each standard door switch is furnished with a mechanical lock-in device for use when only one door switch is installed. When two or more door switches are connected in series, a single, separately mounted short-circuiting switch is installed in an accessible location to avoid the possibility of overlooking any of the door switches when the changeover is made.

When a single door switch at an outer door is connected in parallel with door switches at inner doors, only the door switch at the outer door is provided with a lock-in device, and the lock-in devices are removed from the other outer doors. The location of the control switch is indicated by a plate mounted adjacent to each door switch. The control switch is marked CAUTION—DOOR SWITCH CONTROL. The portion of the short-circuiting switch that connects the door switches in the circuit is marked DARKENED SHIP, and the portion that disconnects the door switches from the circuit is marked LIGHTED SHIP. Personnel should become familiar with the location of the short-circuiting switch in all compartments and the number of doors that it controls.

SPECIAL LIGHTS

Special lights are provided onboard ships for various uses. These lights include (1) flashlights, (2) floodlights, (3) hand lanterns and flood lanterns (fig. 3-20). Lights and lighting fixtures are identified by BuShips symbol numbers (1 thru 399), military standard numbers (MS. no.), federal stock numbers, military specification numbers, or NavShips drawing number. The NavShips Standard Electrical Symbol List (NavShips 0960-000-4000 dated October 1965), lists the lights and lighting fixtures in current use on naval ships. Fixtures are listed in NavShips symbol number order along with the MS or NavShips drawing number, and federal stock number (FSN).

Floodlight

The floodlight (fig. 4-20B) is identified by NavShips symbol number 300.2, military

77.47

Figure 4-20.—Special lights.

11394

standard (MS17338), and federal stock number H6230-889-1559. It consists of a splashproof housing equipped with a rain shielded, hinged door secured with a trunk type latch. The 300-watt lamp is a sealed-beam type.

The lamp housing is trunnioned on a yoke which in turn is mounted on a shock absorbing base. The light is secured in elevation by a clamp on the yoke. Train positioning is accomplished by friction within the shock absorbing base. Each floodlight is furnished with a three-conductor cable (including a green lead to ground the metal housing) for connection into the lighting circuit.

Larger 500-watt floodlights (not shown), using a nogul screw base lamp are also widely used. Floodlights are installed on weather decks at suitable locations to provide sufficient illumination for the operation of cranes and hoists, and the handling of boats. New high-level illuminating floodlights are being developed for evaluation by Ship System Command. Ships deployed in coastal patrol in Southeast Asia require adequate illumination for nighttime apprehension and search of small craft.

Lanterns

Two types of dry battery powered lanterns are available for installation in certain strategic locations to prevent total darkness if the lighting power fails. One model is hand operated. The other is operated automatically by a relay when the regular power fails.

HAND LANTERN, MANUALLY OPERATED—The BuShips symbol number 100.2, MS 17231, lantern (fig. 4-20C), consists of a watertight plastic case containing two type BA-200/U (6 volt), batteries CONNECTED IN PARALLEL. It includes a sealed beam lamp, rated at 5 volts, but operated at 6 volts (when the batteries are new) to increase the light output. A rigid handle is secured to the top of the case. The lantern is operated by a toggle switch, the lever of which is convenient to the thumb. When the batteries are fresh, the lantern can be used continuously for approximately 8 hours before the light output ceases to be useful.

Manually operated lanterns are installed as an emergency source of illumination in spaces that are manned only occasionally. These lanterns are also used in certain areas to supplement the relay-operated lanterns.

Manually operated hand lanterns must not be removed from the compartments in which they are installed unless the compartments are to be abandoned permanently.

NavShips symbol no. 104 (not shown) is a dry battery type (hand carrying or head attaching) lantern used for damage control purposes and is generally stored in damage control lockers. This lantern's battery container may be clipped over the wearer's belt, the lamp and reflector assembly may be hand held or worn on the head or helmet of repair party personnel by using a headband attached to the light.

Lantern, Relay Operated

The relay operated lantern is similar to the manually operated type except that the relay housing is mounted topside of the lantern case (fig. 4-20D) in place of the handle. The 115-volt a-c version is identified by symbol 101.2. Symbol 102.2 identifies the 115-volt d-c type. A three conductor cable (including a green conductor to ground the relay metal frame) is provided for connection into the lighting circuit. THE RELAY CONTROLLED LANTERN MUST ALWAYS BE INSTALLED WITH THE RELAY UPPERMOST. This specific arrangement of the relay prevents a proven fire hazard, which would be caused by liquid electrolyte (formed from battery exhaustion) draining into the (otherwise inverted) relay housing.

Relay-controlled lanterns are assigned to spaces in which it is necessary to maintain practically continuous illumination. These spaces include essential watch stations, control rooms, machinery spaces, battle dressing stations, and at accesses, companionways, and escape passageways leading from compartments (where personnel are stationed or quartered) to the weather deck. These lanterns must not be installed in magazine or powder-handling spaces in which fixed or semifixed ammunition is handled), or in any location in which explosion-proof equipment is required.

The lantern relay is connected in the lighting circuit (in the space in which the lantern is installed) on the power supply side of the local light switch that controls the lighting in the space concerned. Thus, the relay operates and causes the lamp in the lantern to be energized from its batteries only when power failure occurs, not when the lighting circuit is deenergized by the switch. If the space is supplied with both

77.48

Figure 4-21.—Lighting distribution system, schematic diagram.

40282-41397

Figure 17-22. —RHI-scan presentation.

The rotary transformer is a variable-ratio transformer with one primary winding (the rotor) and two secondary windings (the stator). The voltage ratio between the primary winding and each secondary winding changes when the rotor is turned.

The rotor is connected mechanically to the radar antenna. Thus, when the antenna turns, the rotor turns, and the voltage ratio changes. One secondary voltage varies as the sine of the angle of antenna rotation; the other secondary voltage varies as the cosine of the angle of antenna rotation.

The plan position indicator operates as follows: Trigger pulses from the timer (synchronizer) are fed to both the transmitter and the one-shot monostable multivibrator. The one-shot multivibrator generates negative gate pulses that are applied to the trapezoidal-voltage sweep generator and the cathode of the CRT.

The output of the trapezoidal-voltage sweep generator is fed to a power amplifier. The output of the power amplifier is applied to the primary of the rotary transformer. The secondary voltages of the rotary transformer are trapezoidal and have amplitudes that depend on the antenna position.

Figure 17-23. —Block diagram of a PPI-scope system.

1127 8C11

73.98

Figure 4-22.—Delta-delta transformer connections.

of the load that can be carried by two transformers connected in open delta to the load that can be carried by three transformers in closed delta is

$$\frac{P_V \text{ (open delta)}}{P_\Delta} = \frac{\text{E line I line}}{\sqrt{3}\text{ E line I line}} = \frac{1}{\sqrt{3}}$$

= 0.577 or 57.7 percent of the load that can be carried by 3 transformers. Thus, in an open delta connection, the line current must be reduced so as to not exceed the rated current of the individual transformers.

In large ships the transformer banks are installed near the lighting distribution panels that are located some distance from the generator and distribution switchboards or switchgear groups. In smaller ships the transformer banks are located near the generator and distribution switchboard or switchgear groups, and energize the busses that supply the lighting circuits.

The lighting distribution system feeders, mains, and submains are 3-phase circuits. The branches are single-phase circuits and are so connected that the loads on the 3-phase circuits are as nearly balanced as possible.

The emergency lighting system consists of 120-volt, 3-phase, 60-cycle, 3-wire circuits supplied from the emergency generator and distribution switchboards. The circuits to the automatic bus transfer equipment, lighting mains from the emergency lighting feeders, feeder junction fuse boxes, and feeder distribution fuse boxes are 3-phase circuits. If an emergency power system is not installed, an alternate supply from a separate ship's service generator and distribution switchboard or switchgear group must be provided for the services selected in accordance with the basic principles applying to an emergency system.

Automatic bus transfer equipment is installed at load centers, distribution panels, or loads that are supplied by both normal and alternate and/or emergency feeders. This equipment is used to select either the normal or alternate source of the ship's service power, or to obtain power from the emergency distribution system if an emergency feeder is also provided.

D-C LIGHTING SYSTEM

In ships having d-c, 240/120-volt, 3-wire, ship's service power the ship's service lighting feeders are 240/120-volt, 3-wire circuits, and the branches are 120-volt, 2-wire circuits. The lighting load is arranged to provide satisfactory load balance under all conditions.

The emergency lighting feeders are 240/120-volt, 3-wire, d-c circuits, and the branches are 120-volt, 2-wire, d-c circuits.

The 3-wire d-c circuits were formerly installed on all large vessels. They are still used on older vessels, and on surface ships requiring mostly d-c power such as converted merchant ships with large deck machinery loads. Present Navy practice is NOT to ground the neutral (or either leg) of a 3-wire system, but some systems with grounded neutral may be found on older ships or conversions.

DETECTION OF FAULTS IN LIGHTING CIRCUITS

Troubles in 3-wire, d-c systems are located by making tests in their branch circuits, by using the same techniques described in chapter 7 of this training course for 3-wire a-c circuits and their branch circuits.

In addition to the usual tests for open circuits and grounds, look for possible unequal load distribution. This is done by comparing the voltage readings obtained at all branches. Unequal load distribution on the two legs of the system causes high voltage on one leg while low voltage appears on the other leg. High voltages resulting from such unbalance produce short lamp life while the low voltages cause poor illumination.

Unbalanced systems are corrected by removing one or more of the branches from the heavily loaded leg and reconnecting it to a lightly loaded leg in the same (or another) system.

MAINTENANCE

The intensity of illumination produced by a lighting installation begins to depreciate at the time the system is placed in operation. This depreciation in the lighting system is due to the decrease in efficiency of the lamp (with use) and to the decrease in reflecting efficiency of the surrounding bulkheads and overhead, resulting from the natural deterioration of the surface with age.

The deterioration of an incandescent lamp is caused by blackening of the inside of the bulb because of the oxidation of the tungsten filament. The light output of a tungsten filament lamp near the end of its normal life is about 80 percent of the initial output. The depreciation of a fluorescent lamp is caused by blackening at the ends of the tube due to the exhaustion of the active material on the electrodes.

The depreciation of the light caused by the accumulation of dirt, dust, and film on the lamps and fixtures greatly reduces the efficiency of a lighting system. The actual loss of light from this cause will depend on the extent to which oil fumes, dust, and dirt are present in the surrounding atmosphere, and on the frequency with which the fixtures are cleaned.

In the design of lighting installations, a maintenance factor is used to compensate for the difference in the average illumination obtained initially when the lamps and fixtures are new and the resulting average illumination maintained in service. The amount of depreciation will vary from 25 to 45 percent, corresponding to a maintenance factor of 55 to 75 percent and depends on the type of fixtures, the system of illumination employed, the material of the reflecting surfaces (bulkheads and overhead), the local conditions of dust and dirt, and of the frequency of cleaning the fixtures and repainting the bulkheads and overhead. As previously stated, a maintenance factor of 70 percent is used unless otherwise shown on the standard plan of the installed fixtures.

LIGHTING FIXTURES

The lighting system should be maintained at its maximum efficiency because artificial light has an important bearing on the effectiveness of operation of a naval vessel. All lighting fixtures should be adequately cleaned at regular intervals of about two to six weeks to prevent a waste of energy and low intensity of illumination. The frequency for the cleaning periods depends on the degree of prevalence of dirt, dust, and oil fumes in the surrounding atmosphere, and on the type of fixtures installed in the spaces.

Cleaning

The schedules for cleaning the lighting fixtures should be developed to suit the conditions and requirements aboard individual vessels. Lamps and fixtures should be inspected at frequent intervals and cleaned when dirt, oil film, or salt incrustation are first detected. The bulkheads and overhead should be kept clean also as an aid in maintaining the deficiency of the lighting system.

When a fixture requires cleaning, turn off the light and remove the glassware (if any), the lamp, and, if practicable, the reflector (if any). Wash the glassware, lamp, and reflector with soap and water. Avoid the use of strong alkaline and acid detergents when washing aluminum reflectors. Rinse the washed parts with clean, fresh water to which a few drops of ammonia are added to remove the soap film. Dry the parts with a soft cloth and replace them in the fixture.

REPLACING LAMPS, SEALS, AND GASKETS

The NavShips symbol number 92.2 (FSN, H6210-299-7703) watertight fixture (fig. 4-23) consists of a flanged globe that is secured to the base of the fixture by a securing ring. Two globes are available for use with this fixture, the white diffusing globe (FSN H6210-702-5773) or red diffusing globe (FSN H6210-702-2263). The inside surface of the flange fits against a molded-rubber gasket (one-fourth of an inch square) fitted in a circular groove in the bottom of the base. The outside surface of the flange is provided with a centering, molded-rubber gasket. A brass slipring is inserted between the centering gasket and the securing ring. The purpose of the slipring is that of a compression washer when the securing ring is tightened on the base. The entire assembly serves as a watertight seal. Always be very certain that the finished assembly serves that purpose.

To replace a burned-out lamp in this fixture, unscrew the securing ring with a spanner wrench, remove the globe, and replace the burned-out lamp with a new one. Inspect the one-fourth of an inch gasket in the base, and the centering gasket on the outside of the flange and replace with new gaskets if they are worn or deteriorated. Insert the globe and tighten the securing ring onto the base.

To avoid unnecessary waste, use judgment to determine when an old lamp should be replaced. If blackened, but still operative, lamps that are removed from service should be retained on board until allowances of new lamps are received. Then the old lamps should be destroyed or turned over to shore activities, depending on the circumstances.

The majority of the difficulties encountered with fluorescent lights are caused by either wornout or defective starters, or by damaged or expended lamps. Hence, when abnormal operation of a fluorescent fixture is observed, the difficulty can usually be remedied by replacing either the starter or the lamp or both.

HAND LANTERNS

To ensure satisfactory operation of hand lanterns, the batteries should be checked at least once every 3 months. The batteries are checked by operating the lantern and observing the brightness of the lamp. When observed, if the emitted light is dim, the batteries should be replaced immediately.

77.49

Figure 4-23.—Symbol 92.2 watertight fixture.

Lanterns that are located in spaces in which the normal temperature is consistently above 90° F should be checked more often. For example, in boiler rooms it may be necessary to replace the batteries weekly to ensure adequate service from the lanterns.

In addition to checking the batteries, the operation of the relays in lanterns should be checked at least once every 3 months, by deenergizing the lighting circuit to which the relay is connected. When the circuit is deenergized, the relay should operate and automatically turn on the lantern. The circuit may be deenergized by pressure exerted on the push switch located on the relay housing.

PORTABLE FLOOD LANTERNS

As previously stated, the degree of charge in a portable flood lantern is determined by observing the charge indicator balls through the

plastic windows in the battery case. The batteries should be charged as soon as possible after the green ball (10 percent discharged) has sunk to the bottom. The lanterns should be checked at least once a week to determine if the green indicator balls are floating. If they are not floating, the battery should be charged at a rate of 1 1/2 to 2 amperes until all indicator balls are floating at the indicator line. If the battery is completely discharged, it will require from 20 to 25 hours to recharge it. After the charging voltage has remained constant at 10 volts for one hour, discontinue the charging.

When necessary, add pure water to keep the electrolyte level at the indicator line marked on the front of the cell. Do not add enough water to bring electrolyte level above the line because overfilling nullifies the nonspill feature of the battery and may cause the electrolyte to spurt out through the vent tube. However, if the electrolyte level is not at the indicator line, the charge indicator balls will not indicate correctly the state of charge of the battery.

FLASHLIGHTS

Flashlights are checked by switching them on for 3 minutes. If there is a noticeable decrease in light intensity during the interval, the batteries should be replaced with fresh cells. All flashlights should be given this test every 6 weeks.

SAFETY PRECAUTIONS

When a lighting system is installed, the illumination is a fixed rather than a controllable factor. This is especially true if the work cannot be located or positioned to improve the seeing task. It is natural to move the work closer to the light source when seeing is difficult, and when this can be done, improvement in visibility usually results. When the seeing task is prolonged to any appreciable length of time, improvement in visibility is not the only factor to be considered. It is also necessary to take into account the quality of the lighting as affected by glare and the background illumination.

GLARE

Glare is light that hinders, rather than aids vision. It may come from an exposed light source in the field of view (direct glare) or from some shiny surface that reflects a bright source of light toward the eye (reflected glare). In either case, glare is objectionable because it is unpleasant and can cause eyestrain, headache, and fatigue.

Many navy lighting fixtures provide some protection against direct glare from the usual viewing angles, but in many locations it is impossible to mount fixtures so that no part of a bare lamp is in the field of view. Other fixtures have no shielding at all. In a naval vessel it is more important for the lighting fixtures to be simple and rugged, and to provide the essential illumination than to produce entirely adequate and comfortable illumination.

The best protection against the harmful effects of glare aboard ship is the realization by all hands that prolonged exposure to glare should be avoided. Usually, it is possible to position the work and place yourself so that you will not face any of the exposed lamps or uncomfortably bright, reflected-glare spots. If this is not practicable, shield your eyes with a visor.

Always use the proper size lamp in every fixture. For example, glare is invariably produced if a 100-watt lamp is used in a fixture that is designed for a 50-watt lamp. Install shielded fixtures in areas where extended critical seeing tasks are required. Never use exposed lamps or unshielded globes in such spaces. Replace burned out lamps immediately.

If a lamp shatters in its socket, turn off and tag the switch that controls the fixture before attempting to remove the lamp base. Always install and remove fuses with fuse pullers, never with your bare hands. Wiring and rewiring fixtures should be accomplished only by qualified Electrician's Mates and only after authorization has been obtained from the proper authority. When repainting compartments, do not spray paint on the reflecting surfaces of lighting fixtures. Paint will materially reduce the reflection factor of the reflecting surfaces and decrease the illumination.

BACKGROUND ILLUMINATION

The quality of the lighting is affected by the ratio of illumination on the working area to the illumination on the surroundings. The eyes do not remain constantly fixed on any task until it is completed. Instead, they frequently (often involuntarily) glance from the work for a few seconds. If a great difference exists between the brightness of the work area, the pupils of the eyes (which automatically adjust to the amount

of light entering the eyes) must make an adjustment every time the eyes glance away from, and back to, the work. The muscles of the eyes ordinarily will not be overworked if the ratio of brightness of the work to brightness of the surroundings does not exceed 10 to 1. However, if the ratio of brightness is appreciably greater than 10 to 1, eye fatigue will result if the work is continued for a prolonged period. Avoid extreme brightness contrasts between work and background. When lighting fixtures are installed beyond the work area that would illuminate the background, turn on these lights.

DARK ADAPTATION

When a person leaves a brightly lighted area and enters a darkened (not completely dark) area, he immediately experiences an impairment of vision. At first he sees little or nothing but as his eyes become adapted to the darkness, objects become discernible, and gradually more and more of the objects are visible, depending on the level of illumination. For most practical purposes, dark adaptation can be considered complete after approximately 25 to 30 minutes. The time required to reach a given state of dark adptation depends on the intensity of the previous stimulation. The higher the intensity, the longer is the period required for dark adaptation.

When dark adaptation must be maintained, the eyes should be guarded against exposure to white light. If it is necessary to enter an area illuminated by white light, wear red goggles. If the red goggles are not available, close one eye because dark adaptation in one eye is independent of that in the other.

DARKENED-SHIP CONDITION

When darkened-ship condition is ordered, check every door switch installation aboard ship to determine that all lock-in devices or short-circuiting switches are set at the DARKENED SHIP position.

Inspect the light traps to determine that they are free of all obstructions. A light colored object of any appreciable size placed in a light trap might be sufficiently illuminated by the interior lighting to be visible beyond the safe limit. Note the positions of the hand lanterns when entering a compartment so that you can find them without delay when they are needed.

ELECTRICAL HAZARDS

Safety precautions must always be observed by persons working around electrical circuits and equipment. Shipboard conditions are particularly conducive to the severity of shock because the body is likely to be in contact with the ships metal structure and the body resistance may be low because of perspiration or damp clothing.

Despite a fairly widespread but totally unfounded popular belief to the contrary, low voltage (115 volts and below) circuits are very dangerous and can cause death where the resistance of the body is lowered by moisture and especially when current passes through the chest. Show the same respect for the 115-volt lighting circuits as you show for the 450-volt circuits. Practice safety as if your life depended on it, because it does.

CHAPTER 5

SEARCHLIGHTS

This chapter describes the types of searchlights now used in the Navy and acquaints the Electrician's Mate with their proper operation, care, and maintenance.

Naval searchlights are used to project a narrow beam of light for the illumination of distant objects and for visual signaling. To accomplish its purposes the searchlight must have an intense, concentrated source of light, a reflector that collects light from the source (to direct it in a narrow beam), and a signal shutter (to interrupt the beam of light).

Searchlights are classified according to size of reflector and light source. The three general classes are the (1) 24-inch, (2) 12-inch, and (3) 8-inch searchlights. The 24-inch searchlight is of the carbon-arc type; the 12-inch light is either of the incandescent or inert-gas type; and the 8-inch light is of the sealed-beam incandescent type.

New developments in searchlights are now being made. At this time the Naval Ship Systems Command is testing new 18 inch and new 12 inch searchlights. These new lights will use xenon lamps, operate on direct current, and be capable of instant restart while hot.

24-INCH CARBON-ARC SEARCHLIGHT

The 24-inch carbon-arc searchlight (fig. 5-1A) is used primarily for signaling, and secondarily for navigational purposes. It consists of a (1) stationary pedestal, (2) turntable with arms, (3) drum with iris and signaling shutters, and (4) carbon-arc lamp. The turntable is supported on the pedestal and can rotate continuously in train; and the drum, which provides a housing for the lamp, is trunnioned on the turntable arms and can be elevated or depressed through angles of 110° and 30°, respectively.

PEDESTAL

The pedestal is secured to the searchlight platform, or base, and provides a mounting for the turntable and main power switch. The turntable shaft is supported on two large ball-bearing assemblies inside the pedestal (not shown) to allow the turntable and arms to rotate continuously in train.

The Main Power Switch is mounted inside the pedestal and is operated by a handle that protrudes from the switch cover. Terminal tubes through the pedestal provide entrances to the searchlight for the d-c supply cable and the remote signaling key circuit (fig. 5-1A).

TURNTABLE AND ARMS

The turntable and arms, which support the drum, provide a mounting for the shutter switch, train clamp, elevation clamp, and elevation stowing lock. Three collector rings mounted on the turntable shaft (not shown) supply power to the lamp and the remote signaling key circuit.

SHUTTER SWITCH.—The shutter switch is an indicating snap-action rotary switch located on the turntable below the (removable) access plate to the terminal board inside the turntable. This switch must be in the ON position to operate the signaling shutter mechanism by means of the local or remote signal key.

TRAIN CLAMP.—The train clamp is mounted on the turntable below the shutter switch (fig. 5-1B). The searchlight can be secured in any position of train by turning the clamp clockwise.

TRAIN STOWING LOCK.—The train stowing lock is located on the turntable opposite the train clamp (fig. 5-1A). It consists of a spring-loaded pin that engages one of four slots located 90° apart in the top of the pedestal. The

A0PII
11403

77.50.1

Figure 5-1A.—24-inch carbon arc searchlight. (Front View.)

searchlight is located by dropping the pin into any one of these slots. To unlock the searchlight, pull out the pin and turn it clockwise.

ELEVATION CLAMP.—The elevation clamp is mounted on the upper part of the right turntable arm (fig. 5-1A). The searchlight can be secured in any position of elevation (between stops) by turning the clamp clockwise.

ELEVATION STOWING LOCK.—The elevation stowing lock is located on the right turntable arm near the elevation clamp (fig. 5-1A). It consists of a spring-loaded pin (similar to the train stowing lock) for locking the searchlight in either the horizontal (normal) or vertical position.

DRUM

The drum, or barrel, is essentially a sheet-steel shell that provides an enclosure for the lamp. It is equipped with trunnions that are supported by bearings mounted on the turntable arms to allow the drum to be elevated or depressed through angles of 110° and 30°, respectively. Handles are provided at the front and rear of the barrel for swinging the searchlight in train and in elevation to direct the beam of light. The barrel includes the (1) lamp housing, (2) front door and dome glass, (3) iris shutter, (4) sector-vane (signaling) shutter, (5) rear door and reflector, and (6) ventilating system.

11404
CORE

LAMP HOUSING.—The lamp housing is a rectangular section welded on the bottom of the barrel to provide an enclosure for the lamp base. The lamp base, or box, is equipped with four mounting lugs that fit on rails to support the lamp box inside the lamp housing.

FRONT DOOR AND DOME GLASS.—The front door is mounted on hinges welded to the left side of the barrel (fig. 5-1A). It can be latched in the fully open position and is secured in the (normally) closed position by means of six latches.

The dome glass is mounted in the front door by means of a retaining ring to close the front end of the drum and protect the light source. The glass is heat resistant; its surface is precision ground to a curve (dome) that results in only a slight increase in beam spread, and a shape that is highly resistant to shock. However, the latest 24-inch searchlights are equipped with a flat, tempered glass that is considerably stronger and less susceptible to breakage from gunfire than is the dome glass.

IRIS SHUTTER.—The iris shutter is mounted as a removable assembly inside the drum directly behind the front door (fig. 5-1A). It is provided to maintain the drum substantially light-tight when it is desired to shut off the beam of light without extinguishing the arc. It can be used also to vary the size of the drum opening and hence the amount of light in the searchlight beam. The iris shutter must not be used as a signaling shutter.

SIGNALING SHUTTER.—The signaling shutter is a radial-vane shutter mounted inside the drum behind the iris shutter (fig. 5-1B). It is spring actuated to close and is manually opened by an operating handle on the forward right-hand side of the drum. It can be automatically opened by local and remote signaling keys in the shutter operating circuit. If the shutter switch is in the ON position, the signaling shutter will open when the key is closed. The shutter can be latched in the OPEN position when the light is used for illumination.

REAR DOOR AND REFLECTOR.—The rear door is hinged to the left side of the barrel (fig. 5-1B). Similar to the front door, it can be either latched in the fully OPEN position or secured in the (normally) CLOSED position by means of six latches.

The reflector is mounted in a recess of the rear door by means of spring clips and stops. It has a parabolic reflecting surface with the concave side turned toward the light source. The light rays that pass from the light source to the reflector surface are reflected back in a beam essentially parallel to the axis of the reflector. The light source must be small and at, or close to, the focal point of the reflector to obtain a sharp beam in which all of the reflected light rays are parallel to each other and to the reflector axis.

The materials used in searchlight reflectors are Stellite, Hastelloy, aluminum with a special Alzac finish, chromium-plated steel, and rhodium-plated copper. Stellite is the most satisfactory reflector material and is used in all 24-inch searchlights. It has a reflectivity of about 65 percent, is relatively unaffected by arc fumes, and is highly resistant to corrosion by salt water.

ARC-IMAGE SCREEN.—The arc-image screen is located on the upper right-hand side toward the rear of the drum (fig. 5-1B). It is a ground-glass screen upon which a lens system projects an image of the arc. A line is inscribed on the screen to indicate the correct position of the end of the positive carbon when it is at the focal point of the reflector.

The arc-image screen is equipped with a hinged cover. A mirror, mounted on the inside of the cover, can be adjusted so that the operator at the rear of the searchlight can observe the arc image in the mirror.

PEEP SIGHT.—The peep sight (not shown) is located below the arc-image screen on the center line of the drum directly opposite the arc. It contains a dense-colored glass light filter through which can be observed the arc and heads.

The peep sight is provided with a cover that is pivoted on the drum. The cover is closed when the peep sight is not in use to protect the glass and to prevent the emission of light.

VENTILATING SYSTEM.—The ventilating system is necessary to remove the gases produced by the arc and to prevent deterioration of the parts exposed to the intense heat of the arc. The lamp must be extinguished if the ventilating system does not operate satisfactorily.

11403

77.50.2

Figure 5-1B.—24-inch carbon-arc searchlight. (Rear View.)

The ventilating system is mounted on top of the drum and consists of a d-c motor that drives an exhaust fan. The motor is connected across the arc terminal studs and is controlled by the main power switch. It is rated at one-sixth horsepower and operates on 125 volts when the lamp is starting, and it operates on 65 to 70 volts when the lamp is in continuous operation.

The air enters baffled openings in the bottom of the lamp housing and at the sides of the drum. It passes over the inside of the dome glass, the front and rear of the reflector, and directly upward through the center, along the inner surface of the drum, and up through the head-supporting column. The air that is drawn up through the head-supporting column is exhausted through a small vent in the top of the obturator on the positive head. All of the air is drawn through the fan at the top of the drum and is exhausted downward over the outer surface on the left side of the drum.

CARBON-ARC LAMP

The carbon-arc lamp utilizes a high intensity d-c arc between special cored carbon electrodes. It is designed for operation with an arc-ballast resistor (located below deck) supplied from the ship's 120-volt, d-c power. The arc current is adjusted for 75 to 80 amperes with an arc voltage of 65 to 70 volts. The arc-ballast resistor is connected in series with the arc to limit the starting current, stabilize the arc, and absorb the difference between the line voltage and arc voltage.

The function of the lamp mechanism is to hold and control the carbons to produce a source of light (always) at the focus of the reflector. The lamp consists of the positive head, negative head, and lamp operating mechansim (fig. 5-2). The positive and negative heads are secured to the head-supporting column mounted on the lamp base, or box, that contains the mechanism for automatically operating the lamp. The automatic features of rotating and feeding the positive carbon, feeding and retracting of the negative carbon, starting the arc, and providing ventilation are accomplished by the lamp (feed) motor and associated equipment contained in the lamp base.

Carbon Arc

As previously stated, the lamp utilizes a high-intensity, d-c arc between special carbon electrodes. The carbons, consisting of hard-carbon shells with cores of special materials, are mounted in geared heads. The current is conducted to the carbons through spring-backed, metal brush contacts that press against the carbons. The head assemblies are insulated so

77.51

Figure 5-2.—Carbon-arc lamp.

To apply trapezoidal voltages to the two push-pull amplifiers, a center-tapped resistance network is connected across each of the two secondary windings of the rotary transformer. Network R1 produces two voltages (e_1 and e_2) of equal amplitude and opposite polarity, which are applied to one push-pull amplifier. Likewise, network R2 produces two voltages (e_3 and e_4) of equal amplitude and opposite polarity, which are applied to the other push-pull amplifier. For simplicity, only the waveforms of e_1 and e_3 are shown in figure 17-23.

Trapezoidal voltages e_1 and e_2 produce sawtooth sweep currents i_1 and i_2, respectively. Trapezoidal voltages e_3 and e_4 produce sawtooth sweep currents i_3 and i_4, respectively. The angular position of the radial sweep line at any instant depends on the relative amplitudes and the phase relationship of the sawtooth sweep currents at that instant.

Sawtooth sweep currents i_1 and i_2 are equal in amplitude, but opposite in polarity. Likewise, i_3 and i_4 are equal in amplitude, but opposite in polarity. For simplicity, only the waveforms of i_1 and i_3 are shown in figure 17-23. The relative amplitudes and polarities of i_1 and i_3 (also of i_2 and i_4) vary as the rotary transformer is rotated. This causes the radial sweep line to rotate in synchronism with the radar antenna (which is geared to the rotary transformer).

In general, plan position indicators used in conjunction with rotary transformers also use clamping circuits (clampers). The clamping circuits insure that the scanning spot always starts from the same point on the PPI screen.

Negative gate pulses are applied to the cathode of the PPI CRT to intensify the electron beam during each sweep period. The electron beam is intensified to the point where the radial sweep line is barely visible. When echo signals are applied to the control grid of the CRT during each sweep period, the brightness of portions of the radial sweep line is increased.

SWEEP SYSTEM

The various types of deflection and sweep circuitry required for a simplified radar indicator system are shown in figure 17-24. Also shown are the waveforms for this indicator system when set for a 30-mile range sweep.

Negative trigger pulses from the timer are applied to the sweep multivibrator. When a negative trigger pulse is applied to it, the sweep multivibrator causes a switching action which initiates the sweep voltage in the PPI sweep generator.

When the sweep voltage reaches a predetermined level, the sweep-limiter tube conducts, and causes a second switching action. As a result, the sweep multivibrator produces positive and negative rectangular pulses. The PPI sweep generator, on the other hand, produces a trapezoidal voltage.

The trapezoidal voltage is amplified by the PPI sweep amplifiers, and then applied to the synchro driver (power amplifier). The output of the synchro driver is applied to the rotor of a synchro resolver.

The synchro resolver has two stator windings and one rotor winding. The rotor shaft is mechanically coupled to the radar antenna. When the antenna rotates, the synchro-resolver rotor turns, and trapezoidal-sweep voltages of varying amplitude are induced in the synchro-resolver stator windings. The amplitude of the induced sweep voltages, at any instant, depends on the angular position of the rotor winding with respect to the stator windings of the synchro resolver.

The induced sweep voltages are amplified by the PPI deflection amplifiers, and then applied to the deflection coils of the PPI-scope. As a result, a radial sweep line is produced on the PPI screen. Because of the mechanical coupling between the radar antenna and the synchro-resolver shaft, the radial sweep rotates in synchronism with the antenna.

The negative rectangular pulses from the sweep multivibrator are applied to the clamping tubes and the CRT of the PPI-scope. The clamping tubes insure that the PPI electron beam always starts its sweep trace from the same point on the PPI screen.

The negative rectangular pulses applied to the CRT intensify the scope electron beams during the sweep time. This produces a faintly visible trace on the scope.

Indicator blanking during nonsweep time is accomplished by the use of an intensity gate circuit. This is discussed in chapter 16 of this course.

Radial Sweep Line

The radial sweep line on the screen of a plan position indicator is obtained by sweeping the electron beam from the center to the edge of

that only the brush contacts can conduct current to the carbons.

The positive carbon is aligned with the optical axis of the reflector, and the negative carbon is inclined at an angle of 16° to the positive carbon. In operation, the negative carbon burns away to a taper and is fed forward to maintain substantially constant voltage across, or current through, the arc. On the other hand, the core of the positive carbon vaporizes and forms a hollow crater that contains an intensely luminous ball of gas. The positive carbon is rotated continuously about its axis to prevent unsymmetrical burning away of the carbon around the crater and the consequent spilling out of the luminous ball, which is the major source of light. The positive carbon is also fed forward to maintain the crater at the focal point of the reflector, as indicated by the line inscribed on the arc-image screen.

The appearance of the high-intensity arc viewed in the arc-image screen (when burning under different conditions) is illustrated in figure 5-3. When the arc is burning properly, the luminous ball is in the crater, and a TAIL FLAME extends about 6 inches above the positive-carbon tip in a vertical plane through the axis of the positive carbon. If the tail flame shoots off to one side or the other, instead of toward the top of the drum, the alignment of the heads should be checked with the alignment gages, and corrected. If the arc current is too low, the appearance of the luminous ball is not very pronounced, and if the arc current is too high, the luminous ball will appear to extend toward the negative carbon. Excessive arc current is also indicated by a thin, black tongue of soot appearing in the center of the tail flame.

The lamp can be focused by the LAMP-FOCUSING SCREW at the rear of the lamp box. Turning this screw moves the lamp forward or backward on the mounting lugs that slide on rails in the lamp housing.

Both the positive and negative carbons are slowly consumed and must be fed gradually toward the arc. The electrode sizes and burning time for a set, or trim, of carbons can be obtained from the manufacturers' instruction book, furnished with the equipment, or from Chapter 9660 of the NavShips Technical Manual.

77.52

Figure 5-3.—Appearance of high-intensity arc.

Positive Carbon Drive

In addition to continuously rotating the positive carbon to prevent unsymmetrical burning away of the crater, the positive carbon must be fed forward as fast as it burns away to maintain the luminous ball of gas at the focus of the reflector. The positive carbon is carried in the center of the positive head, which is rotated continuously by the lamp (feed) motor through direct gearing (fig. 5-4). The positive carbon is fed by two serrated rollers that are driven by the positive-head gearing.

Continuous rotation of the positive carbon is accomplished by the bevel ring gear, A, that is driven by the rotating positive drive shaft. Gear A is keyed to a hollow shaft, one end of which provides an eccentric mounting for the shaft of pinion D. Pinion D meshes with gear C, which is keyed to detent wheel B and rotates with it. Detent wheel B and gear C are mounted on, and friction coupled through, a ball-bearing sleeve to the hollow shaft attached to gear A. As gear A turns the hollow shaft, detent wheel B and gear C turn, and pinion D (with the associated positive-head gearing) revolves with it. Thus, the positive carbon is rotated, but does not feed (move along its axis) because pinion D does not turn on its own axis.

11408

77.53

Figure 5-4.—Schematic diagram of carbon-arc lamp.

1409

Intermittent feeding of the positive carbon is accomplished when the positive feed shaft operates the detent to prevent detent wheel B and gear C from rotating. As gear A turns the hollow shaft, pinion D now turns on its own shaft as it is carried around the circumference of gear C by the eccentric mounting on the hollow shaft. Pinion D turns the worm gear and positive-head gearing that drive the serrated rollers. Thus, the positive carbon is intermittently fed and rotated simultaneously.

The positive-carbon feed can be operated either automatically by a thermostat system, or manually by holding IN the positive-carbon feed button at the rear of the lamp housing.

The THERMOSTAT SYSTEM consists of a thermostat switch in the circuit of an electromagnet (fig. 5-5). The thermostat switch has two bimetallic strips attached to an insulated block. These strips bend with heat and are assembled so that bending, due to changes in the ambient temperature, is the same in both strips. A contact is mounted on the free end of each strip, which closes when the rear strip is heated more than the front strip.

A lens, mounted on the head-supporting column, collects light rays from the arc and projects them through a window in the top plate of the lamp box where they converge on the thermostat. The projection of the positive-carbon is of the correct length (nine-sixteenths inch) when the converging rays strike the space between the thermostat strips. In this position, the thermostat contacts are open and the positive carbon is rotated by the positive head but is not fed into the arc.

As the positive carbon burns away, the concentrated spot of light moves out of the space between the strips and strikes the rear strip, causing it to bend and close the contacts. The contacts complete the circuit to the positive-feed magnet (electromagnet), which operates the positive-feed shaft to prevent the rotation of the detent wheel, B, on the positive head (fig. 5-4). This action causes the pinion, D, to drive the serrated rollers through the positive-head gearing to feed the positive-carbon toward the arc. When the carbon is fed to the proper position and the light source is again centered on the space between the thermostat strips, the rear strip cools and opens the contacts to deenergize the circuit of the electromagnet and stop the forward feeding of the positive carbon. The positive-carbon feed is nonreversing and thus cannot pull the positive carbon back.

77.54

Figure 5-5.—Thermostat system of carbon-arc lamp.

Negative Carbon Drive

The negative carbon is fed forward and backward as it burns away to control the arc length and thus maintain the proper current through the arc, or the proper voltage across it. The desired normal value of arc current or voltage is set by adjusting the tension of a spring that opposes the pull of an electromagnet in the negative-feed control circuit.

If the negative-carbon drive is current controlled, the electromagnet (current-regulator coil) is connected in series with the arc. The arc current is fixed by the setting of the negative-feed control and is independent of the

COPY 11410

line voltage and the resistance connected in series with the arc, provided they do not vary too widely from their normal values. Conversely, if the negative-carbon drive is voltage controlled, the electromagnetic (voltage-regulator coil) is connected across the arc. The arc voltage depends on the line voltage and the setting of the arc-ballast resistor, which is adjusted to the value that provides the most efficient operation.

Although the principle of operation is similar for both the current and voltage control of the negative-carbon feed, only the current control is explained in this chapter.

The negative carbon is carried in the non-rotating negative head and is fed forward or backward by two serrated rollers that are driven by the lamp (feed) motor through gearing (fig. 5-4). The direction of motion is controlled by a feed coil and a retract coil in the negative-drive mechanism.

The negative-drive mechanism contains a shaft that is geared to the feed motor and rotates continuously (fig. 5-4). The shaft is supported on needle bearings in the frames of the FEED COIL and RETRACT COIL. An armature is pinned to the shaft through a slot and is free to slide a limited distance along the shaft and it rotates with the shaft. The clutch disk is located between two hubs on opposite ends of the armature. When neither coil is energized, the hubs rotate free of the clutch disk.

When the feed coil is energized, the armature is pulled back so that an armature hub bears against the rim of the clutch disk. This action transmits motion (caused by friction between the rim of the clutch disk and the armature hub) to the serrated rollers to drive the negative carbon toward the positive carbon. When the retract coil is energized, the armature is pulled in the opposite direction, causing a reversal of the direction of rotation of the clutch disk. This action reverses the direction of rotation of the serrated rollers to drive the negative carbon away from the positive carbon.

Current Regulator

The series-current-regulator coil provides the automatic control of the negative-carbon feed. It consists of an electromagnet connected in series with the arc (fig. 5-6). The current through the arc is changed by adjusting the tension of the armature spring that opposes the pull of the electromagnet. The spring tension is adjusted by means of the ARC-CURRENT ADJUSTING KNOB at the rear of the lamp housing. Turning the knob clockwise increases the spring tension and the arc current. Conversely, turning the knob counterclockwise decreases the spring tension and the arc current.

The arc current flows through the series coil and as the carbon burns away; the length of the arc is increased, thereby increasing the resistance and decreasing the current flow. This action actuates the armature, which carries the movable contact, A, to complete the circuit to the magnetic clutch that drives the negative carbon.

When the lamp is operating at the proper current, the movable armature contact A, is held midway between contacts 1 and 2 by the balanced pull of the armature spring and the current coil.

When the arc current is low, the pull of the spring is greater than that of the current coil and pulls the movable contact, A, against contact 1. This action places voltage from taps L and M of the resistor across the negative feed coil of the magnetic clutch.

When the arc current is high, the pull of the current coil exceeds that of the spring and pulls the movable contact, A, against contact 2. This action places voltage from taps L and M of the resistor across the retract coil of the magnetic clutch.

When the lamp is started, the negative carbon is in contact with the positive carbon, the starting current is high, and the voltage across the electrodes is low. In this case the pull of the current coil greatly exceeds the pull of the spring, and regulator contact A is pulled against contacts 2 and 3. This action short circuits the 140-ohm resistor, thereby compensating for the reduction in voltage across the carbon electrodes and allowing approximately normal current to flow through the negative retract coil. Retracting the negative carbon forms the arc.

Lamp Circuits

The ship's 120-volt, d-c power is supplied to the searchlight through the searchlight switchboard. The 2-conductor supply cable from the switchboard enters the pedestal through a terminal tube and is connected to a rotary, snap-action, ON-OFF, main-line power switch (fig. 5-7). The 2-conductor, remote-signal

11411

77.55

Figure 5-6.—Schematic wiring diagram of lamp control circuit.

cable also enters the pedestal through a terminal tube. The supply and signal circuits are fed through three collector rings, as indicated in the figure.

The negative and R (remote-signal) terminals on the turntable terminal board are connected to the shutter operating unit through the shutter switch. The signaling keys are connected across the incoming signal circuit and if the shutter switch is in the ON position, the signaling shutter will open when the key is closed.

Shutter Operating Mechanism

The SHUTTER OPERATING MECHANISM consists of a limited-rotation, d-c motor that is connected mechanically through gears to the sector vanes of the shutter. The armature of the shutter motor is supplied with 65 to 70 volts through the signaling keys. The field of the shutter motor is energized when the shutter switch and the power switch are in the ON positions.

77.56

Figure 5-7.—Wiring diagram of 24-inch carbon-arc searchlight.

11413

OPERATION

The searchlight has two modes of operations, automatic or manual.

Automatic Control

The arc is started automatically by the negative-feed mechanism. When the power switch is turned ON, the ventilating fan motor and the lamp (feed) motor immediately start and continue to run as long as the circuit to the carbon-arc lamp is energized.

The carbon electrodes are not touching each other; the current through the series-current-regulator coil is zero (fig. 5-6), and the spring holds the movable armature contact, A, against contact 1. The negative feed coil (NFC) in the magnetic clutch is energized, and the negative carbon moves toward the positive carbon. When the negative carbon strikes the positive carbon, the arc current increases to between 125 and 200 amperes. The increase in current through the series-current-regulator coil overcomes the spring tension and pulls the movable contact, A, against contacts 2 and 3. This action compensates for the reduction in voltage across the carbon electrodes (previously described) and energizes the retract coil (NRC) in the magnetic clutch to retract the negative carbon. As the negative carbon is drawn away from the positive carbon, the arc is drawn out and the arc current decreases to a stable value (75 to 80 amperes), determined by the setting of the arc-current adjusting knob and the arc-ballast variable resistor. The arc voltage may drop to 40 or 50 volts during the arc-stabilization period and then gradually build up until the arc is stabilized.

During normal operation the series-current-regulator coil maintains substantially constant current through the arc. The movable armature contact, A, normally operates between contacts 1 and 2 because the variations in arc current are usually small. Contact 3 becomes operative only when the arc current is very high, as when starting the arc, as described previously.

The thermostat will operate the positive-carbon feed when the arc has been held sufficiently long to burn the positive-carbon projection to less than nine-sixteenths inch beyond the obturator. If the positive-carbon tip is slightly ahead or back of the focal line on the arc-image screen after the arc has been established, the automatic feed will quickly bring it into the proper position. However, if the positive-carbon tip is more than one-eighth inch to the right of the focal line, turn the power switch to the OFF position and reset the positive carbon to avoid the possibility of burning the obturator.

Manual Control

The lamp can be manually operated by the controls located at the rear of the lamp box (fig. 5-1B). In addition to the lamp-focusing screw and arc-current adjusting knob, the controls include the positive-carbon crank, positive-carbon feed button, and negative-carbon crank. These controls are spring loaded and are normally held out of engagement with the motor-drive gearing.

The POSITIVE-CARBON CRANK, when pushed IN and rotated clockwise, rotates the positive head and positive carbon. Rotation of the crank automatically disengages the positive head from the motor-driven nonreversible worm by means of the overrunning clutch, which engages only when the lamp motor is driving the mechanism.

The POSITIVE-CARBON FEED BUTTON, when pushed IN, causes the detent to engage the detent wheel and feed the positive carbon forward. The positive carbon can be fed only when the positive head is being rotated, and it cannot be retracted.

The NEGATIVE-CARBON CRANK, when pushed IN and rotated, feeds the negative carbon when turned clockwise and retracts the negative carbon when turned counterclockwise.

The negative-drive mechanism is provided with an electrical interlock (figs. 5-4 and 5-6) that opens the circuit to the magnetic clutch when the manual control is pushed IN so that the automatic negative-carbon control cannot be engaged at the same time.

Complete manual operation of the lamp can be accomplished provided the ventilating system operates satisfactorily when the power switch is turned to the ON position. To start the arc, push IN the positive-carbon crank (fig. 5-1B) and rotate it slowly clockwise; at the same time, push IN the negative-carbon crank and rotate it clockwise until the negative carbon strikes the positive carbon. Then immediately reverse the rotation of the negative-carbon crank to draw out the arc and reduce the current. Excessive current will cause the arc to sputter and give off black soot.

Continuously rotate the positive-carbon crank and note the position of the positive-carbon tip on the arc-image screen. The positive carbon can be fed into the arc by holding IN the positive-carbon feed button as the positive-carbon crank is rotated. Thus, the tip of the positive carbon is maintained at the focal line on the arc-image screen. The positive-carbon crank must be continuously rotated irrespective of the feeding.

To extinguish the arc, turn the power switch to the OFF position.

PREVENTIVE MAINTENANCE

Electrician's Mates must be competent to operate and maintain the several types of searchlights used in the Navy. Repairs and adjustments to searchlights aboard ship are accomplished only by Electrician's Mates who are specifically assigned to such work by the Electrical or Engineer Officer.

Signalmen and other personnel who frequently use searchlights must be carefully instructed on how to operate them. When operating carbon-arc searchlights, personnel must be impressed with the importance of renewing carbons before the positive carbon has burned so short that it cannot be gripped by the feed rollers and fed toward the arc. If the positive carbon is permitted to burn after this condition occurs, the arc burns closer to the positive nose (obturator) and will finally cause it to melt.

Operators must frequently observe the arc of an operating searchlight through the peep sight. They should renew the carbons when the positive carbon is no longer fed forward or when the positive-carbon tip projects less than one-half inch beyond the obturator. An alternate procedure to determine when to recarbon is to look into the drum through the front door, taking care to keep out of the searchlight beam. Replace the carbons when the trailing end of the positive carbon (end not in contact with the arc) disappears into the positive head.

Renewing Carbons

An Electrician's Mate must remove the old carbons and replace them with a new pair. Carbons are always renewed by pairs to ensure optimum performance. Normally, the front and rear doors must be kept tightly closed during the operation of the searchlight. The doors should not be opened for any purpose until the drum is placed in the horizontal position and the searchlight is locked both in train and elevation. Before changing carbons or attempting any work on a searchlight, turn the power switch to the OFF position. Open the rear door until the latch engages. Make sure that the components are cool before touching with the bare hands. Lift the negative-carbon release lever upward and remove the negative carbon by pushing it out through the rear of the negative head. Lift the positive-carbon release lever and remove the stub by pulling it out over the negative head. If the stub is hot, use pliers to remove it.

The positive and negative heads should be reamed before each recarboning to remove the material deposited by the preceding carbons. When using the reamers, the carbon-feed rollers and contacts should be released to prevent the cutting edges of the reamers from damaging these parts. The positive-nose reamer should be inserted from the obturator end, and the negative-head reamer should be inserted from the rear, or release-lever end. Reamers should not be used while the heads are hot unless it is absolutely necessary. However, if it is necessary to ream while the heads are hot, the reamer should be kept turning continuously to prevent its seizure by cooling and contracting of the metal parts.

When the reaming is completed, run the new set of carbons through the heads to be certain that they do not jam. Crooked carbons or those having long cracks, or loose cores should be discarded. Rough spots and blisters can be removed with sandpaper. Adjust the protrusion of the positive carbon from the nose cap, and adjust the arc length in accordance with the values specified for the equipment in the manufacturers' instruction book. The carbons must be centered in their heads and must not touch the nose caps.

After the carbons are renewed, wipe the reflector, front-door glass, thermostat lens, and thermostat window with a clean, dry cheesecloth to remove any carbon deposit. Close the lamp housing, turn the power switch to the ON position and operate the searchlight for about 5 minutes to form the crater in the positive carbon and establish a normal arc. The first 5 minutes is the critical period of operation after a carbon renewal. During this interval, closely observe the arc and all lamp parts for any malfunctioning.

11415
Draft

Cleaning

Each week all of the carbon arc searchlights must be tested by actual operation and the insulation resistance measured. Figure 5-8 shows the front and reverse sides of a maintenance requirement card covering the required minimum weekly maintenance of carbon arc searchlights.

Each month the maintenance listed on figure 5-9 front and reverse are required.

Lubrication

The trunnion and turntable bearings should be greased in accordance with the applicable manufacturers' instruction book as often as an inspection shows this to be necessary.

Lubrication of the lamp mechanism should be limited to the parts specified in the manufacturers' instructions unless they are superseded by Naval Ship Systems Command.

Figure 5-10 lists the required minimum quarterly maintenance to be carried out on each carbon arc searchlight. Remember the MRC contains only the minimum required maintenance. Certain maintenance actions and adjustments are not covered in the MRC's.

Painting

The exterior parts of the drum, trunnion arms, and base of all searchlights must be painted to preserve the metal. Paint must not be applied to bearing surfaces; working members of any part; or to any bolt; locking nut, or part that must be removed for access to the interior. Nameplates, oil cups, and oil holes must be kept free of paint.

The interior surfaces of the drum, including the signaling shutter blades, must be painted a dull black to minimize stray light.

When painting aluminum alloy parts of searchlights, follow the painting instructions issued by the Naval Ship Systems Command.

CORRECTIVE MAINTENANCE

The majority of searchlight repairs are performed by the ship's force. However, reflectors are not repaired aboard ship. If a reflector deteriorates enough to appreciably diminish the candlepower of the light beam, the reflector must be surveyed in accordance with existing instructions and replaced at a naval shipyard.

Removing and Replacing the Reflector

When it is necessary to replace a reflector, engage the train and elevation stowing locks of the searchlight. Remove the rear-door hinge pins and lay the door on blocks with the reflector side up. Remove the eight bolts (fig. 5-1B), each of which is provided with a clip and vertical stop, and lift the reflector from the door.

Install the new reflector in the door and replace the eight bolts. Position the inside edge of the reflector tightly against the vertical stops on the two bottom points of suspension, and tighten the eight bolts. A shim holder is provided on each of the four bottom stops to prevent the reflector from shifting. Replace the hinge pins and close the door. Start the arc lamp and direct the beam perpendicular to a screen or any other suitable plane surface from 10 to 30 feet distant.

Observe the shape of the beam projection on the screen. If the projection is round, the reflector is properly positioned and requires no further adjustment. If it is not round, adjust the point that corresponds with the portion of the beam that is either inside or outside of the projected circle. This adjustment is accomplished by means of a locking screw and a pressure screw located on the outside of the reflector door and opposite the eight securing bolts. These screws are countersunk in the rear door and protected by cover screws.

If a portion of the contour of the beam projection is inside the remainder of the circle, remove the cover screws and loosen the locking screw corresponding to this point and release the pressure screw. Conversely, if a portion of the contour of the beam projection is outside the remainder of the circle, increase the pressure screw corresponding to this point by tightening it. Continue these adjustments until the beam is round, then tighten all eight of the locking screws and replace all of the cover screws.

Adjustments

Proper ALIGNMENT OF THE HEADS is necessary for satisfactory operation of the lamp. The alignment should be checked after the lamp has been removed from, and replaced into, the drum and after the heads have been

M.R. DESCRIPTION

1. Test operate carbon arc searchlight.
2. Measure the insulation resistance of the carbon arc searchlight.

SAFETY PRECAUTIONS

1. Observe standard safety precautions.
2. Use asbestos gloves.
3. Do not open drum while arc is struck.

(Cont'd on Page 2)

TOOLS, PARTS, MATERIALS, TEST EQUIPMENT

1. Used set of carbons
2. Asbestos gloves
3. Voltage tester
4. Safety tags
5. 500-volt Megger
6. Soft cotton rag

PROCEDURE

Preliminary

a. Obtain permission from OOD to test operate searchlight.
b. De-energize circuit and tag "Out Of Service."
c. Ensure drum is locked in horizontal position and cannot be trained.

1. Test Operate Carbon Arc Searchlight.
   a. Open rear door. Test with voltage tester to ensure circuit is de-energized.
   b. Remove carbons.
   c. Insert set of used carbons; ensure feed rollers grip the carbons firmly. Wipe thermostat lens and arc image screen with soft cotton rag. Close the rear door and remove tag.

WARNING: Do not open drum while arc is struck.

Safety Precautions (Cont'd)

4. De-energize circuit and tag "Out Of Service."
5. Ensure drum is locked in horizontal position and cannot be trained.

Procedure (Cont'd)

d. Energize circuit. Observe striking of the arc as viewed at the arc image screen. Maintain constant watch for five minutes to ensure carbons are feeding properly and positive carbon tip remains in focus.
e. De-energize circuit and tag "Out Of Service." Open rear door. Test with a voltage tester to ensure circuit is de-energized.
f. Use asbestos gloves and remove used carbons.
g. Install fresh set of carbons; ensure feed rollers grip the carbons firmly.
h. Shut rear door. Ensure drum is tightly closed.

2. Measure the Insulation Resistance of the Carbon Arc Searchlight.
   a. De-energize searchlight at the switchboard and tag "Out Of Service." Test with voltage tester to ensure circuit is de-energized. Turn lamp switch ON and measure the insulation resistance of entire searchlight circuit at the switchboard.

NOTE: For insulation resistance readings below one megohm take corrective action.

   b. Turn lamp switch OFF.
   c. Remove tags and set up for prescribed operation.
   d. Notify OOD that maintenance on searchlight is completed.

the PPI screen. To obtain azimuth (bearing) indication, the radial sweep line is rotated about the center of the screen, like a spoke of a wheel.

When a sawtooth sweep current is applied to the deflection coil, as shown in figure 17-25, a magnetic field is produced. The magnetic field causes the electron beam to be deflected, thereby producing a radial sweep line. The amount of beam deflection and, consequently, the length of the radial sweep line depend on the amplitude of the sawtooth sweep current.

The direction of beam deflection, and consequently, the position of the radial sweep line, is always perpendicular to the magnetic field. This system uses a fixed deflection yoke with horizontal and vertical deflection coils. Sawtooth sweep currents are applied simultaneously to the two deflection coils. The direction of the radial sweep line obtained depends on the

7. Safety tags

PROCEDURE

Preliminary

a. Obtain permission from OOD to perform maintenance on the searchlight.
b. De-energize circuit and tag "Out Of Service."
c. Ensure drum is locked in the horizontal position and cannot be trained.

1. Clean, Inspect, and Lubricate Feed Rollers and Brush Contact Blocks.

a. Open rear door. Test with voltage tester to ensure circuit is de-energized.
b. Remove, clean, and inspect the metal contact blocks for the carbons. If blocks are rough, smooth them very carefully with a half-round file, taking care not to damage the contour of the contacts. Reinstall contact blocks. Ensure the contact blocks are free to move in their slides.

(Cont'd on Page 2)

LOCATION

Procedure (Cont'd)

c. Clean and inspect the carbon feed rollers. Ensure the knurled edges are sharp enough to grip the carbons securely and do not slip when the lamp is feeding.
d. Apply two drops of oil to the positive hand feed button, manual positive feed, rotating knob, manual negative feed knob, carbon feed motor bearings, and drive rod bearings in base of lamp. Wipe off excess oil with a rag.
e. Inspect all electrical and mechanical fastenings and tighten loose connections. Use lockwashers or jamnuts where necessary to keep connections tight.

2. Lubricate Signal Shutter, Iris Shutter, and Drum Trunnion Bearings.

a. Lubricate signal shutter, iris shutter, and drum trunnion bearings.
b. Shut rear door and ensure drum is tightly closed.
c. Remove tags and set up for prescribed operation.
d. Notify OOD that maintenance on searchlight is completed.

Safety Precautions (Cont'd)

4. Do not open drum while arc is struck.

Tools, Parts, Materials, Test Equipment (Cont'd)

11. Set of fresh carbons
12. 3 ozs Precipitated chalk
13. 6" White line
14. Reamer for positive and negative heads

Procedure (Cont'd)

CAUTION: Do not ream heads when hot unless absolutely necessary. In reaming hot heads, continuous turning is required to prevent seizure by cooling and contraction of the metal parts.

e. Remove lamp element.
f. Use the brush attachment and vacuum the interior of drum. Remove the white deposits with the clean soft rag. Wipe the interior of the drum with a clean rag.

NOTE 1: Cleaning agent for stellite reflectors is standard bright work polish; for glass dome, doors, and glass reflectors, the cleaning agent is absorbent cotton soaked in denatured alcohol dipped in precipitated chalk.

CAUTION: Do not attempt to clean glass door or reflectors when they are hot. Allow them to cool until palm of hand can be held on the surface for half a minute.

g. Apply cleaning agent to the reflector from center to rim. Do not use rotary motion. Before cleaning agent has completely dried, rub lightly with cotton cloth. Use radial motion from center to rim.

NOTE 2: When repeated normal cleaning methods do not remove mars or spots, take corrective action.

h. Vacuum the carbon refuse from the thermostat lens and the top of the lamp element. Use the dusting brush to loosen dirt.

(Cont'd on Page 3)

Page 2 of 3 | CA | MZ7C | LR4 | 15 | 6971 | Q

Procedure (Cont'd)

i. Remove the lamp element side plates. Clean the close fitting working parts of the lamp mechanism by wiping and vacuuming carbon dust and fragments. Lubricate with oil and wipe up excess oil.
j. Reinstall side plates.
k. Wash the lamp heads thoroughly with alcohol to remove all hard graphite.
l. Dry and coat the wearing parts of the lamp head with a mixture of flaked graphite thinned with diesel oil.
m. Inspect all electrical and mechanical fastenings and tighten loose connections. Use lockwashers or jamnuts where necessary to keep connections tight.
n. Reinstall lamp element in drum.
o. Install fresh set of carbons:
p. Remove white line steadying door and shut rear door.
q. Open glass dome door and secure door to handrail with the white line.
r. Repeat step g to clean one side of glass at a time.
s. Remove white line steadying door and shut glass dome door. Ensure drum is tightly closed. Release train brake, train drum to the normal position, and set up for normal operation.
t. Remove tags.

WARNING: Do not open drum while arc is struck.

u. Energize circuit, strike arc, and observe for proper focus. Set up for prescribed operation.
v. Notify OOD that maintenance on searchlight is completed.

Page 3 of 3 | CA | MZ7C | LR4 | 15 | 6971 | Q

98.176

Figure 5-10.—Quarterly MRC front and reverse sides.

reassembled. The alignment (fig. 5-11) is checked according to the following procedures:

1. Release the positive-carbon release lever.
2. Insert the positive-head gage with the pin snug against the obturator.
3. Secure the positive-carbon release lever.
4. Rotate the positive-carbon crank (fig. 5-1B) to bring the gage pin to the vertical (judged by the eye) so that the indication "top" appears upright.
5. Release the negative-carbon release lever.
6. Insert the negative-head gage with the point forward.
7. Secure the negative-carbon release lever (as shown in the figure).
8. Rotate the negative-carbon crank (fig. 5-1B) until gages touch.
9. Loosen screws and shift negative head to bring negative-head gage point to alignment with positive-head gage punch mark.
10. Secure screws.

The ALIGNMENT OF THE OBTURATOR is accomplished by loosening the two screws that secure it to the positive head, adjusting it so that the positive carbon is approximately centered in the opening of the obturator, and tightening the screws. The obturator must not touch the positive carbon.

The ADJUSTMENT OF THE ARC CURRENT is accomplished while the lamp is in operation by means of the arc-current adjusting knob (fig. 5-1B) at the rear of the lamp box. The nominal arc current is set from 75 to 80 amperes by adjusting the knob and using a portable ammeter, A (fig. 5-6) in series with

77.57

Figure 5-11.—Alignment of heads.

114^0

either leg of the d-c power supply for checking the current readings.

When the arc-current adjusting knob is changed at the searchlight, the arc-ballast resistor must also be adjusted to hold the arc voltage between 65 and 70 volts. Turning the arc-current adjusting knob varies the spring tension on the armature of the series-current-regulator coil (fig. 5-6). To increase the arc current, turn the arc-current adjusting knob clockwise, and to decrease the arc current, turn the knob counterclockwise.

All arc-voltage measurements referred to are taken at the searchlight. If readings of the arc voltage are taken at a distance from the searchlight, the voltage drop in the cables must be considered to obtain accurate adjustments.

The ADJUSTMENT OF THE NEGATIVE CONTACT PRESSURE is accomplished by setting the spring pressure on the negative-carbon brush contact by means of the spring adjustment nut (fig. 5-2). If the spring adjustment is too tight, the negative carbon will be gripped excessively and may stick during operation of the arc. Conversely, if the pressure is too loose, a good contact surface cannot be maintained between the negative carbon and the brush contact. The adjustment should be set to obtain the maximum negative-carbon, brush-contact pressure possible without causing the negative carbon to stick during operation of the lamp.

When the proper adjustment of the lamp is attained, a pull of approximately 8 to 10 ounces parallel to the axis of the negative carbon is necessary to pull the carbon from the head with the feed rollers completely disengaged from the carbon. The positive carbon requires no adjustment.

The ADJUSTMENT OF THE THERMOSTAT LENS should be checked when the reflector is replaced and at any time the feed mechanism should fail to maintain the tip of the positive carbon at the proper distance beyond the obturator. The holes for the screws that attach the thermostat-lens frame to the head support (fig. 5-2) are slotted so that the lens can be moved toward, or away from, the support column. This adjustment is made at the factory so that the beam of light from the lens is centered in the space between the thermostat strips when the positive carbon projects nine-sixteenths inch beyond the obturator. Moving the thermostat-lens frame toward the support column decreases the positive-carbon projection; whereas, moving the lens frame away from the column increases the positive-carbon projection.

To adjust the position of the thermostat lens, start the arc and open the power switch as soon as the forward feed of the positive carbon stops. Measure the projection of the tip of the positive carbon beyond the obturator. Restart the arc and operate the lamp until the positive-carbon feed engages. Immediately stop the arc and again measure the projection of the tip of the positive carbon beyond the obturator. If the average of the two projections is equal to the value specified for the searchlight, the adjustment of the thermostat lens is correct. If the projection is not correct, move the thermostat lens until the proper value of the carbon projection is obtained.

The ADJUSTMENT OF THE THERMOSTAT CONTACTS, which are enclosed in the lamp box, is not normally required. The clearance between the contacts should be from one-sixty fourth to one-thirty second inch (fig. 5-5). Definitely ascertain that the openings between the contacts are incorrect before making any adjustments. The proper spacing can be accomplished by bending one of the strips.

The ADJUSTMENT OF THE SERIES CURRENT REGULATOR ARMATURE is accomplished by adjusting the armature contacts so that the clearances between contacts A and 1, and A and 2, are approximately 0.006 inch (fig. 5-6). The clearance between contacts 2 and 3 should be approximately 0.008 inch.

The arc-image screen focal line can be adjusted to divide evenly the position of the positive carbon tip by means of four screws that secure the arc-image screen assembly to the drum.

The ADJUSTMENT OF THE ARC IMAGE SCREEN is correct when the focal line is at the mean of travel of the positive-carbon tip with the positive-carbon projection adjusted to nine-sixteenths inch beyond the obturator and with the lamp focused properly, as subsequently described. During the normal cycle of positive-carbon feeding and burning off, the positive-carbon tip will move along the positive-carbon axis. This movement, when reviewed on the arc-image screen, should not extend more than 0.05 inch either way from the focal line.

The FOCAL POINT OF THE REFLECTOR is the point at which the light source must be located to obtain a concentrated beam of parallel light rays. In a carbon-arc searchlight, proper focus of the arc occurs when the image

11421

of the tip of the positive carbon appears on the focal line of the arc-image screen. The lamp is adjusted to this position by the lamp-focusing screw (fig. 5-1B) at the rear of the lamp box. This focusing screw is threaded into the lamp housing of the drum and connected to the lamp by a focusing latch attached to the lamp base. Removing the focusing latch from the guides frees the lamp from the focusing screw. The lamp-focusing screw has a lock collar that must be backed off when turning the screw, and set up when the proper position of the lamp has been obtained. Turning this screw clockwise moves the lamp away from the reflector, and turning it counterclockwise moves the lamp toward the reflector. If the tip of the positive carbon does not fluctuate about the focal line on the arc-image screen, focus the lamp by turning the lamp-focusing screw until this condition is obtained.

The focal adjustment can be checked by observing the beam at night. If the lamp is focused properly the beam will appear to consist of parallel rays. If the lamp is too near the reflector the beam will spread, and if the lamp is too far from the reflector the beam will converge into an hour-glass shape. The appearance of the beam should be judged from a distance.

TROUBLES.—The conditions that result in operating difficulties of carbon-arc searchlights are considered to facilitate their detection and correction.

If the ARC CURRENT IS HIGH OR LOW and the arc voltage is normal, set the supply voltage to the proper value and adjust the arc-current adjusting knob to obtain the proper current. This adjustment of the arc current changes the arc voltage, thus it is necessary to reset the arc-ballast resistor to obtain the proper voltage (previously described).

If the ARC VOLTAGE IS HIGH OR LOW and the arc current is normal, set the supply voltage to the proper value and reset the arc-ballast resistor to obtain the proper voltage.

The ARC-BALLAST RESISTOR is provided with a clamp-type adjustable connection to permit variation of the amount of resistance in the circuit (fig. 5-7). Proper adjustment of the arc-ballast resistor is necessary for satisfactory operation of the carbon-arc lamp. The adjustable connection on the resistor permits adjustment of the arc voltage of the searchlight. When the arc-ballast resistor adjustable connection is changed, the effect of the change on the arc must be noted immediately.

The arc-ballast resistor must be used only to compensate for permanent changes in the ship's 120-volt, d-c power to the searchlight. It must not be used for making adjustments for transient conditions in the supply voltage.

If the POSITIVE HEAD FAILS TO ROTATE, push IN the manual positive drive coupling, and turn it clockwise (fig. 5-1B). If the coupling cannot be turned and the head does not rotate, inspect the positive-head gearing for mechanical interference of foreign material in the gears. If the head still does not rotate, remove the lamp from the drum and apply 65-volt test leads to the lamp terminals (without the carbons). Determine that the lamp motor drives the worm gear, and also determine that the motor will operate with no load.

If the POSITIVE CARBON DOES NOT FEED, hold IN the positive-carbon, manual feed button (fig. 5-1B). If the carbon feeds with the button held IN, determine that the positive-feed shaft and its detent are free to operate and are free from mechanical interference with the positive terminal. Observe through the front door to determine that the thermostat lens focuses the arc on the center of the glass thermostat window on top of the lamp box when the positive-carbon tip is on the focal line of the arc-image screen. If the arc is not focused on the center of the thermostat window, turn the power switch to the OFF position, lock the drum in elevation, open the rear door, and adjust the position of the thermostat lens. Be certain that the thermostat window is clean.

If the arc is focused on the center of the thermostat window and the carbon still does not feed, remove the lamp from the drum and determine that the armature of the positive-carbon feed magnet is mechanically free, the thermostat contacts have the proper clearance, and the contact surfaces are clean. Apply 65-volt test leads to the lamp terminals without the carbons, and short circuit the thermostat by connecting a lead across the thermostat terminals. Determine that the positive-carbon feed magnet operates. If it does not operate, the magnet is probably open circuited and should be replaced.

If the positive carbon does not feed when the feed button is held IN, observe through the front-door dome glass and determine if the rotation of the positive-head detent wheel has been arrested by the positive carbon feed shaft.

11422

If the detent wheel is not turning, determine that the feed rollers are gripping the positive carbon. If the rollers are digging into the carbon, ream out the positive head. Inspect the rollers and replace them if the teeth appear to be worn. Determine that the positive-carbon brush contact is free to move up and down in its slide.

If the POSITIVE CARBON FEEDS CONTINUOUSLY, determine that the armature of the positive-carbon feed magnet is mechanically free; that the thermostat contacts have the proper clearance and the contact surfaces are clean; and that the positive-carbon brush contact has freedom of movement.

If the POSITIVE CARBON TIP IS HELD AT A POINT AWAY FROM THE FOCAL LINE on the arc-image screen, determine that the positive-carbon projection is correct. The correct positive-carbon projection is obtained by adjusting properly the position of the thermostat lens and the focus of the lamp.

If the MOVEMENT OF THE POSITIVE-CARBON TIP ON THE ARC IMAGE SCREEN IS GREATER THAN ONE-SIXTEENTH INCH FROM EITHER SIDE OF THE FOCAL LINE, remove the lamp from the drum and inspect the thermostat contacts for the proper clearance.

If the NEGATIVE CARBON DOES NOT FEED AT THE START, determine that the negative carbon release lever is in the secured position and then determine if the negative-carbon drive shaft turns. If the shaft turns determine that the rollers are gripping the negative carbon. If the rollers are digging into the carbon, ream out the negative head and decrease the pressure on the negative-carbon brush contact by means of the negative-carbon, brush-pressure adjusting nut (fig. 5-2). Inspect the drive rollers and replace them if the teeth appear to be worn.

Inspect the negative-carbon brush contact for freedom of movement. If the shaft is not turning, remove the lamp from the drum and check the series-current-regulator contacts. Check the resistance of the feed and retract coils of the magnetic clutch. The resistance of these coils should be 57 ohms with an allowable variation of ±4 ohms. Check the electrical interlock (cutout switch) on the negative manual feed and determine that it is closed.

If the NEGATIVE CARBON FEEDS SLUGGISHLY, examine the serrated rollers and determine that they grip the carbon firmly. Remove the carbon and examine the contacts and hose, and ream out any obstructions. Replace the negative carbon if it is damp because a damp carbon will cause sluggish feeding.

If the NEGATIVE CARBON DOES NOT RETRACT AFTER STRIKING THE POSITIVE CARBON, turn the power switch to the OFF position and check the circuit breaker on the searchlight switchboard (fig. 5-7) to determine if it has opened, and set the trip mechanism to a higher value (not exceeding 300 amperes). Reclose the circuit breaker and check the alignment of the heads. Ream the negative head and check the negative-drive mechanism to determine that it is free from mechanical binding.

Remove the lamp from the drum and check the spacing of the series-current-regulator contacts. Check the resistance of the feed and retract coils in the magnetic clutch and replace them if they are open circuited, or if their resistance is not within ±4 ohms of 57 ohms each. Check the resistor that feeds the magnetic clutch coils (fig. 5-6) to determine that proper contact is made and that the resistor is not open circuited. Renew the carbons and set the arc-current adjusting knob, replace the lamp in the drum, and recheck the current setting.

If the ARC BREAKS REPEATEDLY, check the arc voltage and current at the time the arc breaks. The current is usually low when the arc breaks repeatedly, and the arc-current adjusting knob should be turned clockwise until rated current flows. Adjust the arc-ballast resistor to maintain 65 to 70 volts while adjusting the arc current.

If the arc continues to break, remove the lamp from the drum and check the alignment of the heads. Ream the negative head if any obstructions are present. Check the resistances of the feed and retract coils of the magnetic clutch.

If the ARC CURRENT VARIES MORE THAN 5 AMPERES when the lamp is in normal operation, check the contacts on the series-current regulator coil. Adjust the contacts for proper clearances and determine that the contacts are clean. Check the supply voltage and install new carbons if they have become damp.

The length of the arc can be used as a rough check on the current flow. Measure the arc along a straight line from the center of the carbon tips. This is a rough check and no adjustment should be made unless the arc length is off one-eighth inch or more. The arc length can be increased by changing the tap connections

11423

to the arc-ballast resistor to decrease the resistance in the circuit.

If the arc length is one-eighth inch or more off when measured between the center of the carbon tips, the arc length can be decreased by changing the connection to the arc-ballast resistor to increase the resistance of the circuit.

SAFETY PRECAUTIONS

The general instructions and operating precautions must be adhered to by Electrician's Mates, Signalmen, and other personnel when operating or maintaining searchlights.

The assigned Electrician's Mate or lamp operator must be certain that the carbons are properly placed, are firmly gripped by the feed rollers, and make good electrical contact with the current contacts before starting the lamp mechanism of a carbon-arc searchlight. Do not operate the lamp if the ventilating system does not function properly. Do not turn the power switch to the ON position when the carbons are touching, except in the older searchlights that are provided with a hinged negative head for striking the arc.

Frequently observe, on the arc-image screen of an operating lamp, to determine that the positive carbon is properly focused to avoid damage to either head (caused by failure of the carbons to feed properly). A continual or frequent adjustment of the arc focus by means of the lamp-focusing screw indicates a failure of the positive-carbon feed to function properly or other maladjustment that must be corrected.

Turn off the arc and recarbon when the feed rollers fail to engage, and feeding has stopped, or when the positive carbon projects less than one-half inch beyond its nose. Never look directly at the arc. Always view it through the peep sight or arc-image screen.

Under normal conditions the drum must be kept tightly closed during operation of the arc.

Lock the searchlight securely in train and elevation and be certain that the drum is in the horizontal position before opening the front or rear door of a 24-inch, carbon-arc searchlight.

Be certain that the power supply to the shutter motor is deenergized before opening the front door or performing any work inside the drum of a searchlight provided with an electrically operated shutter.

Before attempting to train or elevate a searchlight, be certain that the stowing brakes and locks are disengaged and that the searchlight is free to move.

Be certain that the power switch is in the OFF position before changing carbons. Always use asbestos gloves to remove hot carbon stubs. Recarbon with a pair of carbons and do not use broken or bent carbons. Be certain that the positive carbon does not touch its nose cap and keep the nose cap free from dirt and deposits of carbon dust. Keep the thermostat lens and window clean.

Do not operate the signaling key on the 24-inch searchlight when the signaling shutter is latched open and do not keep a signaling shutter open by holding down on the signaling key.

Keep all electrical contact surfaces clean and free from oil, grease, dust, and moisture. Do not use oil or grease on the positive or negative heads.

When reaming the heads, release the contacts and feed rollers, and do not allow these parts to come in contact with the reamer.

The carbons must be kept sealed in their containers until required. They must be kept dry and protected from any jarring that can cause them to crack or to loosen the cores.

Searchlights that are not in use must be locked in their securing positions by means of the brakes and stowing locks. All openings into the drum must be kept tightly closed unless otherwise ordered.

In case of threatening or inclement weather at sea, canvas covers must be applied and lashed down on all searchlights, except for those designated as ready lights. During heavy weather at sea, searchlights must be secured with the front-door glasses turned inboard.

12-INCH INCANDESCENT SEARCHLIGHT

The 12-inch incandescent searchlight is used primarily for signaling and secondarily for illumination.

CONSTRUCTION

The searchlight (fig. 5-12) comprises the (1) mounting bracket, (2) yoke, (3) drum, and (4) lamp (not shown). The MOUNTING BRACKET permits the searchlight to be secured to a vertical pipe or to a flat vertical surface. The YOKE is swivel mounted on the bracket to allow the searchlight to be rotated continuously

11023

77.58

Figure 5-12.—12-inch incandescent searchlight.

in train. The steel DRUM provides housing for the lamp and is trunnion mounted on the yoke to allow it to be elevated and depressed. Clamps are provided for locking the searchlight in any position of train and elevation.

The SIGNALING SHUTTER is a venetian-blind shutter mounted inside the drum behind the front door. It is held in the CLOSED position by two springs and is manually opened by a lever on either side of the drum. The parabolic metal reflector is mounted on the inside of the rear door.

The LAMP is usually a 1000-watt, 117-volt incandescent lamp having special concentrated filaments that reduce the area of the light beam. The lamp is mounted in a mogul bipost socket. The socket is located in front of the reflector and can be adjusted only slightly. The replacement of the lamp is accomplished through the rear door of the searchlight.

The light source must be at the focus of the reflector for minimum beam spread and maximum intensity. Some types of 12-inch incandescent searchlights are provided with focusing adjustment screws. Other types can be adjusted by loosening the screws that hold the lamp-socket support plate in position. Move the entire socket assembly toward or away from the reflector until the beam has a minimum diameter at a distance of 100 feet or more from the light, and retighten the screws. When checking the diameter of the beam, the rear door must be tightly clamped shut.

A screen hood is provided for attachment to the front door to limit the candle power of the beam, to cut down its range, and to reduce stray light, which causes secondary illumination around the main beam. The hood also provides for the use of colored filters.

TWELVE-INCH SHORT-ARC, MERCURY-XENON SEARCHLIGHT

The Naval Ship Systems Command has developed a mercury-xenon arc lamp that can be installed in the standard Navy 12-inch incandescent signaling searchlights (fig. 5-13). The mercury-xenon arc lamp, when used in these searchlights, produces a maximum beam intensity about 10 times as great as that attained by the incandescent lamp.

The lamp is a 1000-watt short-arc, mercury-xenon lamp requiring 45 amperes to start and 18 amperes to operate. It is supplied from the

77.59

Figure 5-13.—12-inch mercury-xenon searchlight, (rear view showing lamp).

11425
98411

ship's 117-volt, 60-cycle, single-phase power. The lamp consists of two tungsten electrodes spaced about one-quarter inch apart inside a 2-inch diameter quartz bulb. The bulb contains a small quantity of liquid mercury and xenon gas at a pressure of 3 to 5 atmospheres when the lamp is cold (an atmosphere at sea level is equivalent to 14.7 psi). After the arc is started and the lamp attains a stable operating temperature, the internal pressure increases to about 20 atmospheres. The lamp does not produce full-light output until this pressure is reached and all of the mercury has been vaporized. The lamp differs from the incandescent lamp in that it requires a high voltage, r-f current for starting and a ballast for operating it at rated output.

Remember this lamp housing should never be opened while operating or energized. The high voltage (40,000 to 60,000 volts) present plus the danger of the lamp exploding requires the observance of precautions at all times.

LAMP ADJUSTER ASSEMBLY

The lamp adjuster is secured to the top of the searchlight drum and extends inside the drum to provide a mounting for the mercury-arc lamp (fig. 5-14). The assembly affords longitudinal traverse (toward or away from the reflector), horizontal (from side to side), and vertical adjustments of the lamp.

BALLAST UNIT

The ballast unit, located out of the weather near the searchlight, consists of a transformer and five resistors enclosed in a steel box. The unit provides the necessary ballast voltage in series with the lamp to maintain constant current for normal operation.

STARTER UNIT

The starter unit, enclosed in a watertight box, is mounted in the lamp housing. It consists of the necessary components for starting and operating the lamp. The electrical connections from the ballast unit to the starter unit are provided by a cable equipped with a watertight plug.

OPERATION

The electrical circuit of the 12-inch mercury-xenon arc searchlight comprises the (1) starting circuit and (2) operating circuit. The ship's single-phase, 115-volt, 60-cycle power is supplied to the ballast unit through a disconnect switch located adjacent to the searchlight (fig. 5-15).

77.60

Figure 5-14.—12-inch mercury-xenon lamp adjuster assembly.

Starting Circuit

When the lamp is extinguished, whether hot or cold, the internal resistance between electrodes is so high that the arc will not restart by applying normal line voltage. Hence, a special high-voltage r-f circuit is incorporated to provide instant starting, irrespective of whether the lamp is cold or hot. However, the lamp is harder to start while it is hot and at

77.238

Figure 5-15.—Wiring diagram of 12-inch mercury-xenon searchlight.

Figure 17-25.—Electromagnetic aximuth yoke, relationship between sweep direction and yoke position.

relative amplitudes of the two sweep currents. To insure that the deflection caused by the sawtooth is in one direction (fig. 17-26 (A)), the base of the sawtooth must be at zero potential. To position the base of the sawtooth at zero volts, another waveform must be combined with the sawtooth. If the negative portion of a square wave is added to the end of the sawtooth, and if the area of the negative portion of the square wave is equal to the area of the sawtooth, the average of the waveform will be at the base of the sawtooth. (See fig. 17-26 (B).) The current in the deflection coils caused by the sawtooth will be in one direction and the sweep on the scope will start from the same point each and every sweep. The scope is blanked at all times except during the sweep time; therefore, only the correct sweep will be present on the scope. If the square wave is too small, the scope will be undercompensated. If the square wave is too large, (fig. 17-26 (BC), the scope will be overcompensated and an open center will appear on the scope. This open center is undesirable in this circuit.

Circuit Theory

For the following discussion, refer to figure 17-27. The tubes V2 and V3, with associated parts, constitute a multivibrator. In the static state, V2 is conducting and V3 is cut off. An input trigger is applied to the grid of V2; since V2 is conducting in the static state, the trigger must be negative. When the conduction of V2 decreases, the plate voltage rises. This increase in voltage is coupled to the grid of V3, which is driven into hard conduction. The plate voltage of V3 decreases, and this change is coupled to the grid of V2. The discharge of C2 through R5 holds V2 cut off until the sweep-stop tube conducts. The sweep-stop tube is V1, which will be discussed later.

The diode V16 is the switch tube for the sweep generator. In a static state, V16 is conducting and C3 is held at a low-positive voltage. When V16 is cut off, C3 will charge through R12 and R10. V16 is cut off by its cathode being driven to a positive voltage. The cathode of V16 is driven positive when V3 conducts. When V16 is cut off, the charge on C3 increases at a sawtooth rate. The sawtooth is applied to the grid of V1 and V5. V1 is the sweep-stop tube, and it is held cut off in the static state by a positive voltage on its cathode. A voltage divider is formed by R1 and R2 from B+ to ground. R2 is variable, and it is used to adjust the bias on V1. As the voltage on the grid of V1 rises, the bias decreases; V1 will conduct when the bias is overcome. When V1 conducts, a drop in voltage is seen at the right end of R9 and the grid of V3. The decrease in voltage at the grid of V3 will decrease plate current. The rise in plate voltage of V3 is coupled through C2 to the grid of V2, driving V2 into conduction. The plate voltage of V2 decreases and V3 is driven into cutoff, which places the multivibrator back in the static state until another trigger arrives at the grid of V2. The sweep ends whenever V1 conducts. The amplitude of the sawtooth required to drive V1 into conduction is determined by the setting

14140 0611

maximum internal pressure. This circuit is capable of producing a voltage from 40,000 to 60,000 volts. After the arc is started, the lamp will operate on normal voltage of 60 to 70 volts.

The starting circuit includes the step-up transformer, (fig. 5-12), the secondary of which supplies high voltage to an r-f circuit containing a spark gap, capacitor, inductances, and the primary of the pulse transformer. When the spark gap breaks down, r-f oscillations build up in the spark gap circuit, and the primary of the pulse transformer (RF coil). These oscillations are fed to the transformer secondary where high voltage is developed in the circuit comprising the lamp unit (for starting the arc).

When the arc is struck in the lamp, the starting current is limited to about 45 amperes by the reactance of the secondary of the booster transformer in series with the lamp and the parallel combination of the five ballast resistors.

Operating Circuits

To start the arc, turn the power switch to the ON position and press the momentary switch. When the momentary switch closes, the primary of step-up (H-V) transformer as energized. The voltage on the primary is boosted 32 volts above the line supply by the autotransformer action of the booster transformer. The secondary of (H-V) transformer in turn, energizes the r-f circuit to superimpose a high-voltage pulse across the lamp electrodes, causing the arc to start.

Release the momentary switch immediately after the arc is started to disconnect the starting circuit. It is essential that the momentary switch be released as soon as the arc strikes, otherwise the lamp will be overloaded. If the lamp is operated under this condition for a very brief period it will become overheated and fail violently.

Micro switches S3 and S6 are manually operated as a single unit as the searchlight door is opened to provide for deenergizing the starter unit circuits independently of the power switch as an additional safety feature when servicing the lamp circuit.

To extinguish the lamp, turn the power switch to the OFF position.

Preventive Maintenance

The 12-inch short-arc, mercury-xenon searchlight should be kept clean and the trunnion and yoke bearings lubricated with grease applied with an alemite gun.

The reflector and cover glass should be cleaned weekly. The procedures for cleaning these parts are similar to those for cleaning glass and Alzac-finished aluminum reflectors and front-door glasses described for the 24-inch searchlight.

The shutter assembly should be inspected monthly for tightness of screws and fastenings, for ease of operation, and for light tightness. If the return action of the shutter assembly becomes sluggish, lubricate the shutter bearings in accordance with the MRC shown in figure 5-16. Use the lubricant sparingly and do not allow it to contact the quartz envelope of the mercury-xenon lamp. If the shutter action remains sluggish after lubrication, replace the shutter springs.

The searchlight is properly focused when shipped. The service lamp is packed in the repair parts box with three additional spare lamps. When assembling or disassembling the lamp, use the face mask and the gloves provided with the equipment. The lamp is filled, under considerable pressure, with xenon gas and may burst violently if it is dropped or struck. The lamp must not be handled without enclosing it in the protective metal enclosure provided with the equipment.

To replace the short-arc, mercury-xenon lamp, position it in the lamp adjuster assembly with the collar resting on the stop (fig. 5-14). Press the brackets tightly against the metal collars on the lamp and tighten the wing nuts. Connect the lamp leads to the terminal posts on top of the starter assembly and be certain that the leads have a clearance of 1 inch from the nearest metal parts. Connect the short, bottom lead on the lamp to the terminal marked, HV.

Remove finger marks or grease from the quartz arc tube with alcohol or other grease-free solvent, and dry carefully with a clean cloth. Operation of the lamp with finger marks or grease on the surface will cause deterioration of the quartz envelope. Inspect all connections for tightness and, using the face guard and gloves, remove the metal safety shield from the lamp and place it in the repair parts box. Close the door assembly and secure it with the three thumb screws. Plug the power cable from the ballast into the receptacle on the starter box assembly.

SYSTEM	COMPONENT	M.R. NUMBER
Communications and Control	12" Mercury-Xenon Searchlights	EL-9 M-1
SUB-SYSTEM	MAINT. SIGNIFICANT NO. / RELATED M.R.	RATES / M/H
Navigation Equipment	W-1	EM3 / 0.3

M.R. DESCRIPTION
1. Lubricate trunnion and shutter bearings.
2. Lubricate shutter bearing screws and pins.

TOTAL M/H: 0.3
ELAPSED TIME: 0.3 unit

SAFETY PRECAUTIONS
1. Observe standard safety precautions.
2. Ensure lamp is de-energized and cold. Tag "Out Of Service."
3. Exercise caution when working on Mercury-Xenon lamps.

TOOLS, PARTS, MATERIALS, TEST EQUIPMENT
1. Oil can with Symbol 2110 oil
2. Grease gun with VV-G-632 Type B Grade 2 grease
3. Clean rags
4. 4" Screwdriver
5. Voltage tester
6. Safety tags
7. Face guard and gloves

PROCEDURE

Preliminary
a. De-energize circuit and tag "Out Of Service."
b. Test with a voltage tester to ensure circuit is de-energized.

WARNING: If the inside of a Mercury-Xenon lamp is blackened, it must be replaced. Enclose the lamp with the protective metal cover before removing or replacing a lamp. Wear a face guard and gloves when removing or replacing the protective metal guard. These lamps contain gas under considerable pressure and may explode under certain conditions. Do not let grease or oil contact Mercury-Xenon lamps.

1. Lubricate Trunnion and Shutter Bearings.
a. Apply a few drops of oil to the trunnion bearings.
b. Apply one squirt of grease to the zerk fitting located at the stanchion socket.
c. Remove clamps from center shutter rod.

(Cont'd on Page 2)

LOCATION

Page 1 of 2 | CA | 2236 | 1E4 | 84 | 6018 | M

Procedure (Cont'd)

d. Remove the left and right covers from the bearing housing assemblies to lubricate shutter bearings.
e. Apply 4 drops of oil in the hole in the hub of the bearing housing assemblies.
f. Reinstall left and right covers on the bearing assemblies and reinstall clamps.

2. Lubricate Shutter Bearing Screws and Pins.
a. Loosen knurled screws one or two turns. Rotate the entire flange assembly, which contains the lens, counterclockwise approximately 1/4". The entire lens assembly can now be removed to expose the shutter bearing screws.
b. Apply 3 drops of oil to the ends of the bearing screws and to the pins.
c. Reinstall lens assembly and tighten knurled screws.
d. Energize the circuit and remove tags.

Page 2 of 2 | CA | 2236 | 1E4 | 84 | 6018 | M

98.176

Figure 5-16.—Monthly MRC for 12" mercury-xenon searchlight.

To check the focus of the lamp, secure the drum in a level position with the shutter locked OPEN. Turn the power switch ON and direct the beam against a perpendicular, flat surface about 100 feet distant. The spot should be a concentrated image of the arc projected along the axis of the drum.

If the lamp is out of focus, the LONGITUDINAL TRAVERSE ADJUSTMENT is accomplished by loosening the lock screw (fig. 5-14) and sliding the plunger, or focusing handle, in or out to move the lamp toward, or away from, the reflector. This adjustment results in increasing or decreasing the diameter of the projected spot. The focusing handle is provided with two witness marks. When the first witness mark is aligned with the edge of the bushing at the top of the box, the lamp will be positioned at the focal point of the reflector and will produce a concentrated light beam of minimum divergence. When the second witness mark is aligned with this bushing, the lamp will produce a beam with a 4-degree spread. The focus should be adjusted for minimum divergence when the light is used at maximum ranges, and a 4-degree spread for close range operation.

It is seldom necessary to make the horizontal or vertical adjustments of the lamp. However, if these adjustments are required, it is necessary to remove the top cover plate.

The HORIZONTAL ADJUSTMENT is accomplished by loosening the four horizontal screws (fig. 5-14) and sliding the mounting plate to the right or left of center as required, and then retightening the horizontal securing screw.

The VERTICAL ADJUSTMENT is accomplished by loosening the socket-head cap screw and turning the vertical screw (fig. 5-14) to elevate or depress the beam, and then retightening the socket-head cap screw, and replacing the cover, making certain that the gasket is in place.

Corrective Maintenance

If the short-arc, mercury-xenon lamp should fail to light, check the wiring to be certain that the lamp leads clear any metal parts by at least 1 inch. Inspect the safety switches S3 and S6 (fig. 5-15) to determine that they are closed. Secure the shutter in the OPEN position, turn the power switch ON and rotate the starting switch knob counterclockwise; then release it. Observe, through the cover glass, the electrodes of the lamp for signs of arcing. The arc should take place just before the starting switch knob reaches the end of its travel. If arcing is observed and the lamp fails to light, replace the lamp with a new one.

If the lamp still fails to light, check the leads from the HV transformer for high-voltage leaks. Check the circuit to determine if the momentary switch closes.

Safety Precautions

The short-arc, mercury-xenon lamp must be operated with the shutter assembly secured to the drum. To avoid deterioration of the quartz arc tube, remove fingerprints or grease before operating the lamp.

The lamp contains gas under considerable pressure and if dropped or struck it may burst violently. The lamp must not be handled without enclosing it in the protective metal enclosure provided. This precaution applies to both new and burnt-out lamps. Lamps that reach the end of their useful life are potentially dangerous and must be disposed of in the sea. Always use face mask and gloves when assembling or disassembling the lamp to protect the eyes and skin from flying material should the lamp explode.

Before working on the assembly or replacing a lamp, be certain that the safety switches (fig. 5-15) are open and that the plug on the starter unit is disconnected. The safety switches must not be bridged or depressed when personnel are working inside the lamp drum for any reason.

Protect the eyes and skin from direct or reflected rays of lamp during operation. Some of the 12-inch mercury-xenon searchlights have been converted to automatic starting types while others are manually started. For detailed differences in the construction and operation of these two types see the applicable technical manual for the particular type of searchlight installed on your ship or station.

8-INCH, SEALED-BEAM SEARCHLIGHT

The 8-inch signaling searchlight utilizes an incandescent sealed-beam lamp. It is designed to withstand high vibratory shock and extreme humidity conditions, and will operate equally well in hot or cold climates.

This searchlight may be furnished for operation with either a 60-cycle 115-volt transformer

11430

165 OF 327

ED

056 238

MICROCOPY RESOLUTION TEST CHART

NATIONAL BUREAU OF STANDARDS-1963-A

to step the voltage down to 23 volts, or without transformer to operate on 115 volts using the proper rated sealed beam unit. This same unit is available for use on small craft from a 28 volt power source.

Construction

The searchlight (fig. 5-17) consists of the (1) base, (2) yoke, (3) housing, and (4) lamp. The BASE is equipped with a rail clamp for securing the searchlight to the rail. The YOKE is swivel mounted on the base to allow it to be trained through 360°. The HOUSING provides an enclosure for the lamp and is composed of a front and a rear section. The front section comprises the shutter housing, and the rear section comprises the backshell housing. The two sections are held together by a quick-release clamp ring that permits easy replacement of the lamp. The backshell and lamp assembly, when detached, may be used as a portable searchlight. The entire housing is mounted on brackets attached to the shutter housing and supported by the yoke to allow the searchlight to be elevated or depressed. Clamps are provided for securing the searchlight in train and elevation.

77.62

Figure 5-17.—8-inch 60-cycle sealed-beamed searchlight.

The SHUTTER HOUSING contains the venetian blind shutter, which is held closed by springs and manually opened by a lever on either side of the housing. The front of the shutter housing is sealed by the cover glass and a gasket. The rear of the shutter housing is enclosed by a gasket and adapter assembly. The adapter assembly provides a locating seat for the lamp and incorporates a hook and key arrangement that aligns the backshell housing and retains it in position while attaching the clamp ring to hold the two sections together.

Three filter assemblies (red, green, and yellow) are provided and can be readily snapped in place over the face of the searchlight. The shutter vanes can be locked in the open position for use as a spotlight.

The backshell housing provides an enclosure for the 115/23 volt transformer.

Preventive Maintenance

The 8-inch sealed beam searchlight should be kept clean and painted. The electrical contacts should be cleaned with a soft cloth. Do not use abrasives to clean these contacts. The front face of the lamp and the cover glass should be kept clean with water or glass cleaner.

To remove the lamp from the housing for cleaning or replacement, tip the rear end of the searchlight up to its highest position and lock it in place. Release the clamp-ring toggle and remove the clamp ring (fig. 5-17). Remove the backshell assembly by raising it up to disengage it from the hook and tab. Pull the gasketed lamp out of the shutter adapter assembly by gripping the lamp gasket on its periphery and lifting it out to disengage the gasket lugs from the notches in the adapter assembly.

To replace the lamp in the lamp gasket, be certain that the TOP marked on the lamp and on the gasket are aligned and that the lugs of the lamp are firmly seated in the recesses provided in the gasket. To replace the gasketed lamp in the housing, be certain that the lugs are set into the notches in the adapter assembly located inside, and at the rear of, the shutter housing. Set the backshell assembly over the shutter assembly, engaging the shutter hook into the slot of the backshell. Using the hook

as a hinge, carefully swing the lower part of the backshell down to the shutter assembly, engaging the shutter tab into the notch in the rolled edge of the backshell. Be careful to swing the backshell down in a straight line to make direct engagement and to ensure proper positioning of the lamp contacts on the terminals of the lamp. Replace the clamp ring, being certain to have the hinge pin set into the notches of the adapter and backshell assemblies.

11402

CHAPTER 6

MAINTENANCE OF MOTORS AND GENERATORS

This chapter describes procedures for the maintenance of motors and generators. Additional information is contained in chapters 9610 and 9630 of the NavShips Technical Manual.

Proper maintenance is important in ensuring long, satisfactory service of electric motors and generators. The most important factor in the maintenance of electric motors and generators is to keep the equipment clean and free of oil, water, dirt, and other foreign particles. Oil vapor, metallic dust and moisture are present in the air inside a ship. These elements are especially prevalent in the air of machinery spaces where major electric motors and generators are located. All machines require ventilation to dissipate the heat generated by their operation, and since most motors and generators utilize the air within the compartments in which they are located for this purpose, it is apparent that a considerable amount of these destructive elements will accumulate on, and inside, these machines within a relatively short time. Motors and generators must be cleaned frequently, both internally and externally, and particular care must be taken to keep all air ducts clean.

CLEANING MOTORS AND GENERATORS

The importance of keeping all insulation clean must be emphasized. Dust, dirt, and foreign matter (carbon, copper, mica, etc.) tend to block ventilation ducts and increase resistance to the dissipation of heat, causing local or general overheating. If the particles are conducting or form a conducting paste through the absorption of moisture or oil, the winding may be eventually shortcircuited or grounded. Abrasive particles may puncture insulation, iron dust is particularly harmful since the dust is agitated by magnetic pulsations.

The four acceptable methods of cleaning motors and generators are wiping, use of suction, use of compressed air, and use of a solvent.

Wiping with a clean, lint-free, dry rag (such as cheese cloth) is effective for removing loose dust or foreign particles from accessible parts of a machine. When wiping, do not neglect such parts as the end windings, mica cone extensions at the commutator of d-c machines, slip-ring insulation, connecting leads, and terminals.

The use of suction is preferred to the use of compressed air for removing abrasive dust and particles from inaccessible parts of a machine because it lessens the possibility of damage to insulation. If a vacuum cleaner is not available for this purpose, a flexible tube attached to the suction side of a portable blower will serve as a satisfactory substitute. Always exhaust the blower to a suitable sump or overboard when used for this purpose. Grit, iron dust, and copper particles should be removed only by suction methods whenever possible.

Compressed air must be clean and dry when used for cleaning electrical equipment. Air pressure up to 30 pounds per square inch may be used on motors or generators of 50 hp or 50 kw respectively, or less. Pressures up to 75 pounds per square inch may be used to blow out machines that are over 50 hp or 50 kw. A throttling valve should be used on air lines that carry higher pressure than is suitable for blowing out a machine. Before the air blast is turned on the machine, any accumulation of water in the air pipe or hose must be thoroughly blown out, and both ends of the machine must be opened to allow a path of escape for the air and dust. The use of compressed air will be of small benefit if the dust is not suitably removed from the machine. The most suitable method is to attach a suction blower to an opening in the opposite end from the air jet to remove the dirt-laden air.

The use of solvents for cleaning electrical equipment should be avoided whenever possible, however their use is necessary for removing grease and pasty substances consisting of oil and carbon or dirt. Alcohol will injure most types of insulating varnishes and should not be used for cleaning electrical equipment. Solvents containing gasoline or benzine must not be used for cleaning purposes under any circumstances. Carbon tetrachloride is not to be used because of its extremely high toxicity.

APPROVED SOLVENTS

Inhibited methyl chloroform (trichloroethane), FSN GM 6810-664-0388, is one of the principal approved solvents for cleaning electrical equipment. This solvent is less toxic than carbon tetrachloride; liberal ventilation, however, must be provided by exhaust fans or portable blowers if this solvent is used for more than a few minutes.

In the rare cases when means of ventilation are impractical, an air line respirator or oxygen breathing apparatus (OBA) must be used if exposure to the solvent vapors is for more than a few minutes.

Inhibited methyl chloroform is very corrosive in its action on metal and may prove injurious to certain insulation. Before using any solvent, apply it to a small area or sample of the insulation to be cleaned. If it injures the insulation, do not use it. Clean fresh water, preferably warm or hot, may be used as an emergency substitute for inhibited methyl chloroform. Water should be used only as an emergency substitute and the equipment must be thoroughly dried after any application of water.

Do not spray inhibited methyl chloroform on windings. It will collect in pools and do more harm than good. The solvent should be applied by moistening a lintless cloth with the fluid and lightly rubbing the surfaces to be cleaned; repeat the process if necessary to loosen the dirt. After wiping the insulation with solvent it should be thoroughly dried with a clean lintless cloth.

Inhibited methyl chloroform is detrimental to good commutation and should be kept from coming in contact with the commutator or brushes of d-c machines.

Inhibited methyl chloroform should never be used on hot equipment as the accelerated evaporation will increase the toxic hazards.

Trichloroethylene (FSN G6810-184-4794) is another approved solvent, widely used in a vapor process for degreasing metals. It should not be used for cleaning electrical insulation because of its strong solvent action on these materials. The toxic effects of trichloroethylene are similar to those of inhibited methyl chloroform.

Dry cleaning solvent, type II, (FSN W6850-274-5421) is an approved safety type solvent. The fire and health hazards of this solvent have been minimized. The efficiency of this solvent is somewhat less than the previously discussed chlorinated solvents but the hazards to personnel are also reduced.

PRECAUTIONS

During the use of any solvent the following precautions must be observed.

1. Guard carefully against fire.
2. Use vapor-proof or watertight portable lights if supplementary lighting is required.
3. Have fire extinguishers available for immediate use.
4. Prevent possible sparks caused by one metallic object striking another.
5. If a spray or atomizer (not normally used for routine cleaning) is used, ground the nozzle.
6. Avoid saturation of the operator's clothing with the solvent.
7. Provide liberal ventilation by means of exhaust fans or portable blowers.
8. When using inhibited methyl chloroform or trichloroethylene, protect against breathing the fumes, (a chemical cartridge respirator such as a gas mask will not prevent suffocation since the vapors from these solvents displace air and oxygen), cleaning should be done under the observation of someone familiar with artificial respiration.
9. Do not apply solvents on hot equipment or in the presence of open flames. The chlorinated solvents form highly toxic phosgene gas on contact with open flame.
10. No less than two persons should be assigned to cleaning operations in a single compartment.

General signs of fume poisoning by chlorinated hydrocarbons include headache, nausea, mental confusion, and in some instances a kind of drunken behavior similar to that caused by alcohol. When any of the above symptoms are observed, the person should immediately be removed from the toxic atmosphere to fresh air or a well ventilated space.

For additional information on cleaning of equipment by the use of compounds, sprays, or

immersion in solvents refer to NavShips Technical Manual, chapter 9600.

GENERAL MAINTENANCE

The essential points in the maintenance of electric generators and motors are: keep insulation clean and dry and of high resistance, keep electrical connections tight, and keep machines in good mechanical condition.

Keep all small pieces of iron, bolts, and tools away from the machines. Where it is necessary to do any soldering, make sure that no drops of solder get into the windings and that there is no excess of solder on soldered joints which may later break off due to vibration and fall into the windings.

Do not disturb the commutator clamping bolts on d-c machines. Interference with these may make it necessary to turn or grind the commutator to restore it to service.

Other bolts and mechanical fastenings on both the stationary and rotating members should be tightened securely when the machine is installed, checked after the equipment has run for a short time, and thereafter checked at regular intervals to make sure that they are tight. Particular attention should be given to the bolts used to clamp any insulation.

If an inspection of a rotor shows that there is looseness of keys, bolts, or other fastenings, a check should be made for evidence of damage due to this looseness. Such looseness may result in worn dovetail keys, damaged windings, or broken dovetails on the end plates. Two or three drivings (with a punch and hammer) usually will ensure the tightness of the keys, but nevertheless they should be checked regularly.

The banding wire on d-c armatures should be checked at regular intervals to make sure that it is tight.

The outboard bearing on some generators (both a-c and d-c) is electrically insulated from the frame; or the bearing pedestal is insulated from the base and the bearing oil piping to prevent the flow of shaft currents through the bearing. In the former case, insulation is accomplished by means of a shell of insulating material installed between the bearing shell and the bearing housing. In the latter case, the bearing insulation is accomplished by using insulating shims under the pedestal and insulated holding down bolts and dowels. Also insulated couplings are provided in the bearing inlet and outlet oil piping flanges (for force feed bearings). Special attention should be taken to ensure that this insulation is not damaged or that conducting paths around this insulation are not inadvertently provided. For instance, care should be taken when painting machines furnished with insulated pedestals not to paint over the insulating shims, washers, and oil piping couplings. Bearing currents, if of sufficient magnitude, will rapidly ruin a bearing. These currents are caused by electromotive force generated in the shaft and structural parts of a generator unless it is carefully designed and constructed to minimize their occurrence. An insulated bearing (or pedestal) breaks the circuit and protects the bearings from damage so long as the insulation is effective.

Inspect all electrical connections (particularly terminals and terminal board connections) at frequent intervals to make sure they are tight. Loose connections result in increased contact resistance and increased heating which may result in breakdown. Use lock nuts, lock washers, or other means to lock connections which tend to become loose because of vibration. Inspect soldered terminal lugs for looseness or loss of solder, and tighten solderless terminal lugs occasionally. When electrical connections are opened, clean all oil and dirt from contact surfaces before reconnecting. If the contact surfaces are uncoated copper, sandpaper and clean immediately before joining. If the contact surfaces are silver plated, do not use sandpaper. Use silver polish or a cloth moistened slightly with an approved solvent. Coat the finished joint with insulating varnish. Steel bolts for making electrical connections should be zinc or cadmium plated. Make sure that exposed electrical connections are adequately insulated to protect against water and moisture and injury to personnel. This applies especially to exposed connections at terminal straps extending outside the frames of propulsion motors and generators.

When it becomes necessary to disassemble and reassemble a motor or generator, follow the procedures outlined in the manufacturer's instruction book, exercising care to prevent damage to any part of the machine. The machine rotors (a-c revolving field or d-c armature) should be supported, while being moved or when stationary, by slings or blocking under the shaft or by a padded cradle or thickly folded canvas under the core laminations. To lift the rotor, rope slings (separated by a spreader to prevent the slings coming in contact with the a-c rotor

11435

or d-c armature coils) should be placed under the shaft, clear of the bearing journals. If construction of the shaft provides no room for a sling except around the journals, they must be protected with heavy paper or canvas before applying the sling. When the whole unit (stator and rotor) is to be lifted by lifting the stator, the bottom of the air gap must be tightly shimmed unless both ends of the shaft are supported in bearings. It is easily possible, by rough handling or careless use of bars or hooks, to do more damage to a machine during disassembly and assembly than it will receive in years of normal service.

Excessive vibration in electric motors and generators may be caused by an unbalanced rotating part (d-c armature, a-c revolving field, cooling fan, etc.). Therefore, when it is necessary to repair a rotating part in such a manner as to remove or add weight at any point around its periphery, the part must be tested for balance. An unbalanced condition can be corrected by dynamically balancing the part. In dynamic balancing, the test for unbalance is made, with the part turning at normal speed, by determining the exact lengthwise location where whip is maximum, and by spotting the exact radial point at which excessive weight appears. Balancing is effected by removing weight at this point or by the addition of counterweight at a point directly opposite the point of excessive weight. Dynamic balancing requires special equipment operated by specially trained personnel. Repair ships and shipyards are equipped to perform this task.

SLEEVE BEARINGS

Bearings are of two types: SLIDING and ROLLING. The three types of sliding bearings are the right line bearing, in which the motion is parallel to the elements of the sliding surface; journal bearing, in which two machine parts rotate relatively to each other; and thrust bearings, in which any force acting in the direction of the shaft axis is taken up. The type of sliding bearing employed in electric motors and generators is the journal bearing commonly called the SLEEVE bearing. These bearings are used in large equipment, such as turbine-driven ship's service generators and propulsion generators and motors. The bearings may be made of bronze, babbitt, or steel-backed babbitt.

Preventive maintenance of sleeve bearings requires periodic inspections of bearing wear, and lubrication.

WEAR

Propulsion generators and motors and large ship service generators are usually provided with a gage for measuring bearing wear. Bearing wear on sleeve bearing machines not provided with a bearing gage can be obtained by measuring the air gap. It is usually not necessary to measure air gaps on machines which have ball bearings because the construction of the machine is such as to assure bearing alinement. Bearing wear of sufficient magnitude to be readily detectable by air gap measurements would be more than enough to cause unsatisfactory operation of ball bearings and would be detected in this way.

Air gaps on a sleeve bearing machine not provided with a bearing gage should be measured at each end of the machine. Air gaps can be measured with an air gap feeler. This is a machinist's tapered feeler gage with a blade long enough to reach into the air gap without removing the end brackets of the machine. Before making the measurements, clean the varnish from a spot on a pole or tooth of the rotor. A spot should also be cleaned at the same relative position on each field pole of a d-c machine. For a-c machines, at least three and preferably four or more spots spaced at equal intervals around the circumference should be cleaned on the stator. The air gap measurements should be taken between the cleaned spot on the rotor and the cleaned spot on the stator, turning the rotor to bring the cleaned spots on the rotor opposite each of the cleaned spots on the stator.

If one end of the machine is accessible only with difficulty, either of the following procedures may be used.

1. Take several measurements at one end in accordance with the procedure described above, and two measurements approximately 90° apart at the less accessible end. If these two do not differ greatly from the mean of the measurements at the other end, the air gap is reasonably uniform at both ends.

2. Take several measurements at one end of the machine in accordance with the procedure described above, and average these to obtain the average air gap, or obtain the average air gap

11436

Figure 17-26.—PPI-scope deflection saveforms. (A) No compensation or undercompensation; (B) balanced compensation; (C) overcompensation.

of R2. If the arm of R2 is moved down, the voltage at the cathode of V1 increases and the sawtooth on the grid of V1 must rise to a higher amplitude to fire V1. The sweep capacitor must charge for a longer time; therefore, the sweep time and amplitude will increase. R2 is adjusted for the correct amplitude and then R10 is adjusted for the correct sweep time. R2 is the amplitude control and R10 is the sweep time control. If R2 is adjusted first, the two controls will not interact.

The sawtooth at the grid of V5 is amplified and the negative-going sawtooth at the plate is coupled to V7, amplified, inverted, and coupled to the grid of V9. The positive sawtooth applied to the grid of V9 causes the current to increase through the tube at the sawtooth rate. The sawtooth of current through the plate winding of V9 induces a voltage into the secondary, and this voltage causes a sawtooth of current in the secondary.

The sawtooth at the cathode of V6 will be amplified; and from the plate of V6, a positive-going sawtooth will be fed back to the top of R10. The voltage at the top of R10 rises during sweep time, holding the effective voltage constant. The diode V4 is the disconnect tube for the bootstrap circuit.

At the cathode of V9, V6, and V5, a sawtooth of voltage is developed across the unbypassed cathode resistor. In parallel with R27 from the cathode of V5, another network is tied to the ground. This network consists of R22, R21, V13, and R19 to ground. A capacitor C8 is tied from the junction of R22 and R21 to ground. C8 charges to the average of the sawtooth at the top of R21. Therefore, a constant voltage at the plate of V13 will rise to the charge of C8. At the plate of V13, a square wave will be developed as V13 is cut off and on. This square wave is amplified and coupled to the grid of V15. A square wave of current

SM8141

from records of preceding measurements. The average air gap is one-half the difference between the inside diameter of the stator (or field pole arrangement) and the outside diameter of the rotor (or armature), and is not affected by bearing wear. Procure a long, narrow strip of steel. The thickness of the steel strip should be 20 percent less than the average air gap for average air gaps smaller than 0.040 inch; it should be 10 percent less for average air gaps larger than 0.040 inch. Test the air gap by trying to push this strip all the way from one end of the air gap to the other. This test should be made at four points 90° apart, if possible, and if not, at a number of points (not less than three) spaced at approximately equal intervals around the circumference. The test can be repeated with a slightly thicker strip if a closer estimate is needed.

It is more important to have uniformity of air gaps at all points than to have the gap conform exactly to the specified limits. If the air gap at any of the places tested differs from the average air gap by more than 20 percent for average air gaps smaller than 0.040 inch, or by more than 10 percent for average air gaps larger than 0.040 inch, the bearings should be realigned, repaired, or replaced. Usually an inequality of air gaps which is not greater than specified above will not cause unsatisfactory operation. If, however, trouble is experienced, such as vibration or excessive noise which cannot be traced to any other cause than unequal air gaps, it is advisable to realign, repair, or replace bearings to equalize air gaps, even if the measured inequalities are within the limits given.

LUBRICATION

Every precaution should be taken to keep the oil and bearings clean and free from water or foreign particles.

Do not add oil while the machine is running. This affords an opportunity for oil mist or spray to escape from the bearing housing and be blown on the machine windings.

Bearings having an overflow gage should be filled until the oil is about one-sixteenth inch from the top of the gage. If the machine is equipped with an oil filter gage, the gage should be filled to the manufacturer's oil level mark, or (if no mark is available) the gage should be between two-thirds and three-quarters full at all times. Be sure that the gage glass and piping to the gage are clean or the glass will give false indications of the oil level. If the bearing has neither an overflow gage nor an oil filter gage, fill to a level such that the oil ring dips into oil to a depth of about half the shaft diameter.

When the bearing and bearing housing are in good condition, there should be no loss of oil. If the proper oil level cannot be maintained without adding oil, it is probable that oil is leaking from the bearing. Be sure the oil sight gage connection to the bearing is tight. Much of the oil that leaks out of a bearing is drawn into the machine by the cooling air and sprayed onto the windings where it causes oil soaked dirt to collect. This condition tends to cause insulation failure. If oil leakage is suspected, carefully clean and chalk the shaft outside the bearing, the outside of the bearing housing, and the parts of the rotor adjacent to the bearing. If the machine is throwing oil, discoloration of the chalk will so indicate after a short run. This test will not be dependable unless the chalked part is perfectly clean at the beginning of the test. If leakage is found, the labyrinth seal in the bearing housing should be corrected to make it effective. Another possible source of leakage is from the vent with which some labyrinths are provided. Make sure that any such vent is not stopped up and that it terminates in still air of atmospheric pressure where there is no current of air over the vent that will suck oil out of the bearing housing or oil vapor out of the vent into the machine. Such oil leakage is often due to overfilling the bearing or trying to fill the bearing through the vent.

Bearing oil should be renewed semiannually. Drain the oil off by removing the drain plug, then flush the bearing with clean oil until the drained oil flows clean.

OIL RINGS AND BEARING SURFACES

An opening is provided in the top of the bearing for checking the condition of the oil rings and bearing surfaces (fig. 6-1). Periodic inspections are necessary to make certain that the oil ring is rotating freely when the machine is running and is not sticking due to the motion of the ship. With the machine stopped, the bearing surfaces should be inspected for any signs of pitting or scoring.

TROUBLE ANALYSIS

Earliest indication of sleeve bearing malfunction normally appears as an increase in the operating temperature of the bearing. This

11437

77.239

Figure 6-1.—Diagram of an oil-ring lubricated bearing.

increase is due to the heat generated in the extremely sensitive oil film separating the rotating journal from the bearing surface and is governed by the slipping or shearing of the oil molecules. When the bearing is operating satisfactorily, the film temperature remains stable; but when the equilibrium of the oil film is interrupted, rapid and sharp changes occur in the temperature of the oil film. Oil is supplied under pressure from a central system to sleeve bearings in some large machinery, such as turbine-driven ship's service generators.

Thermometers are usually inserted in the discharge line from the bearing as a means of visually indicating the temperature of the oil as it leaves the bearing. Thermometer readings are taken hourly on running machinery by operating personnel. However, a large number of bearing casualties have occurred in which no temperature rise was detected in thermometer readings, and, in some cases, discharge oil temperature has actually decreased. Therefore, after checking the temperature at the thermometer, a follow-up check should be made by feeling the bearing housing whenever possible. Operating personnel must thoroughly familiarize themselves with the normal operating temperature of each bearing so that they will be able to recognize any sudden or sharp changes in bearing-oil temperature. Many large generators are provided with bearing temperature alarm contactors which are incorporated in the ship's alarm system. The contactor is preset to provide an alarm when the bearing temperature exceeds a value detrimental to bearing life. If bearing malfunction is indicated, the affected machinery should be secured as soon as possible. A motor with overheated sleeve bearings should be unloaded, if possible, without stopping the motor. If stopped immediately, the bearing may seize. The best way to limit bearing damage is to keep the motor running at light load and supply plenty of cool, clean oil until the bearing cools down.

Any unusual noise in operating machinery may also indicate bearing malfunction. Whenever a strange noise is heard in the vicinity of operating machinery, a thorough inspection must be made to determine its cause. Excessive vibration will occur in operating machinery with faulty bearings, and inspections should be made at frequent intervals in order to detect its presence as soon as possible.

Corrective maintenance of sleeve bearings is accomplished by personnel of machinery ratings aboard ship or by shipyard personnel. Usually, repairs of this type are of such magnitude as to require lengthy shipyard availability for accomplishment; hence, the importance of practicing proper preventive maintenance of sleeve bearings must be emphasized.

BALL BEARINGS

Rolling, antifriction bearings are of two types: ball and roller bearings. Basically, all rolling bearings consist of two hardened steel rings, hardened steel rollers or balls, and separators. The annular, ring-shaped, ball bearing is the type of rolling bearing used most extensively in the construction of electric motors and generators used in the Navy. This bearing is further divided into three types dependent upon the load it is designed to bear—(1) radial, (2) angular contact, and (3) thrust. Examples of these three bearings are shown in figure 6-2.

The rotating element of an electric motor or generator may subject a ball bearing to any one or a combination of three loads — radial, thrust, and angular. Radial loads are the result of forces applied to the bearing perpendicular to the shaft; thrust loads are the result of forces applied to the bearing parallel to the shaft; and angular loads are the result of a combination of radial and thrust loads. Because the load carried by the bearings in electric motors and generators is almost entirely due to the weight

11638

77.66

Figure 6-2.—Typical ball bearings.

of the rotating element, it is apparent that the method of mounting the unit is a major factor in determining the type of bearing employed in its construction. In a vertically mounted unit, the thrust bearing would be used; while the radial bearing is common to most horizontal units.

The preventive maintenance of ball bearings requires periodic checks of bearing wear, and adequate lubrication.

WEAR

Measuring air gaps to determine bearing wear is not necessary on machines equipped with ball bearings because the construction of the machine is such as to ensure bearing alignment. Ball bearing wear of sufficient magnitude as to be readily detected by air-gap measurements would be more than enough to cause unsatisfactory operation of the machine.

The easiest way of determining the extent of wear in these bearings is to periodically feel the bearing housing while the machine is running to detect any signs of overheating or excessive vibration, and to listen to the bearing for the presence of unusual noise. The indications thus obtained are comparative, and caution must be exercised in their analysis.

When testing for overheating, the normal running temperature of the bearing must be known before the test can be reliable. Rapid heating of a bearing is indicative of danger. While a bearing temperature uncomfortable to the hand may be a sign of dangerous overheating, it is not always so. The bearing may be all right if it has taken an hour or more to reach that temperature; whereas, serious trouble can be expected if that same temperature is reached within the first 10 or 15 minutes of operation.

The test for excessive vibration relies to a great extent on the experience of the person conducting the test. He should be thoroughly familiar with the normal vibration of the machine in order to be able to correctly detect, identify, and interpret any unusual vibrations. Vibration, like heat and sound, is easily telegraphed, and a thorough search is generally required to locate its source and to determine its cause.

Ball bearings are inherently more noisy in normal operation than sleeve bearings, and this fact must be borne in mind by personnel testing for the presence of abnormal noise in the bearing. A good method for sound testing is to place one end of a screwdriver or steel rod against the bearing housing and the other end against the ear. If a loud, irregular grinding, clicking, or scraping noise is heard, trouble is indicated. As before, the degree of reliance in the results of this test depends on the experience of the person conducting the test.

The one sure method of checking ball bearing wear is also the most difficult. In this test, the bearing caps or other covers provided are removed and the actual condition of the bearing is observed. Each ball bearing should be inspected in this manner at least every two years. The condition of the lubricant in the bearing may be checked at this time; however, no attempt must be made to disassemble double-shielded or sealed-for-life bearings (fig. 6-3).

77.67

Figure 6-3.—Motor equipped with permanently lubricated ball bearings.

11439

LUBRICATION

IMPROPER GREASING PROCEDURES ARE A FREQUENT CAUSE OF DERANGEMENTS TO ROTATING ELECTRICAL MACHINERY PROVIDED WITH GREASE-LUBRICATED BALL BEARINGS. The trouble is generally caused by forcing an excessive quantity of grease into the bearing housing, with either one or both of the following results:

(1) Grease is forced through the bearing housing seals and onto the windings and, in the case of d-c machines, onto the commutators where it causes deterioration of insulation and eventually results in grounds or short circuits.

(2) The excessive quantity and pressure of grease in the bearing housing result in churning, increased temperatures, rapid deterioration of the grease, and ultimate destruction of the bearing.

The following instructions apply to equipment except oil-lubricated bearings, synchros, and similar devices where friction must be maintained at an absolute minimum, and equipment for which approved lubrication charts or other specific instructions are furnished by the Navy. Except for the equipment to which they do not apply, the following instructions should be carefully observed in order to avoid failure of electrical equipment because of improper greasing practices:

Motors and generators provided with bearings that should be lubricated with grease are now normally delivered from the manufacturer with the grease cups removed from the bearing housings and replaced with pipe plugs. The grease cups are delivered with the onboard repair parts or special tools. It is recommended that grease cups (fig. 6-4) be attached to electric motors and generators only when the bearings are being greased. When the grease cup is removed from the bearing housing after a bearing has been greased, the hole which remains should be plugged with a suitable pipe plug. When this procedure is used, the grease cups should remain in the custody of responsible maintenance personnel and can be stored in the workshop or toolroom. This procedure is particularly advantageous when the motors and generators maintained by a particular group of maintenance personnel need only relatively few different sizes of grease cups. This procedure should also be followed for motors and generators which have been supplied with grease cups attached to the machine. CARE SHOULD BE TAKEN TO MAKE SURE THAT A GREASE CUP IS CLEAN BEFORE IT IS USED TO ADD GREASE TO A BEARING AND THAT THE PIPE PLUG USED TO REPLACE THE GREASE CUP AFTER GREASING IS ALSO CLEAN.

77.68

Figure 6-4.—Grease-lubricated ball bearings.

Some electric motors and generators may be equipped with oil-lubricated ball bearings. Lubrication charts or special instructions are generally furnished for this type of bearing and should be carefully followed by personnel maintaining the equipment. In the absence of other instructions, the oil level inside the bearing housing should be maintained approximately level with the lowest point of the bearing inner ring. This will provide enough oil to lubricate the bearing for a considerable operating period, but not enough to cause churning or overheating.

One common method by which the oil level is maintained in ball bearings is the wick-fed method. In this method, the oil is fed from an oil cup to the inside of the bearing housing through an absorbent wick, which also filters the oil and prevents leakage through the cup in

11440

the event momentary pressure is built up within the housing. A typical wick-fed, oil-lubricated ball bearing is shown in figure 6-5.

The frequency with which grease must be added depends upon the service of the machine and the tightness of the housing seals, and should be determined for each machine by the engineer officer. Ordinarily, the addition of grease will not be necessary more often than once in six months. When a bearing housing is too full of lubricant, the churning of the grease generates heat which in turn causes deterioration of the grease. Under these conditions the grease separates into oil and minute abrasive particles, becomes increasingly stickly, and tends to seal the bearing against fresh lubricant until the resulting friction, heat, and wear cause failure of the bearing.

77.69

Figure 6-5.—Wick-fed ball bearing.

Greasing Procedures

Bearings which normally operate at a temperature of 194° F (90° C) or below should be lubricated with grease in accordance with Military Specification MIL-G-18709, Stock Nos. W9150-235-5544 and W9150-235-5564.

To avoid the difficulties caused by an excessive amount of grease, grease should be added only when necessary, and, when grease is added, it should be done as follows:

1. Run the machine to warm up the bearings.
2. Wipe the outside of grease fitting and drain plug free of all dirt.
3. Remove bearing drain plug, and make sure the passage is open by probing with a clean screw driver or similar implement.
4. Remove pipe plug on top of the grease pipe (open grease pipe by probing as above). Select the proper grease cup, empty and clean out the grease cup (top and bottom). Install the bottom portion of the grease cup on the grease pipe.
5. Fill the bottom portion of the grease cup with clean grease, fill the top portion (cap) of the grease cup only half full of grease.
6. Thread the half filled cap of the grease cup onto the fully filled bottom of the grease cup and screw it down as far as it will go (by hand). Keep the machine running continuously while adding grease.
7. Repeat steps (5) and (6) above until clean grease begins to emerge from the drain hole.
8. Continue to run the machine and let grease run out of drain hole until drainage stops (normally about 30 minutes). Remove grease cup and replace pipe plug.
9. Replace the drain plug.
10. DO NOT USE A GREASE GUN TO LUBRICATE BEARINGS UNLESS THERE ARE NO OTHER MEANS AVAILABLE. If a grease gun must be used, remove the drain plug in the bearing housing while greasing and use extreme care to avoid inserting too much grease or applying more than just enough pressure to get the grease into the housing.

RENEWAL OF GREASE WITHOUT DISASSEMBLING THE BEARING HOUSING.—Renewal of grease without at least partial disassembly of the bearing housing is not recommended. In any case, renewal of grease without at least partial disassembly of the bearing housing should not be attempted unless the following conditions apply:

1. The machine is horizontal. In vertical machines, there is no adequate means of protecting the windings against displaced lubricant.
2. A suitable fitting is provided for admitting grease. If a grease-gun fitting is provided, it should be replaced by a grease cup.

3. The drain hole on the bearing housing is accessible. Drain pipes do not permit satisfactory escape of displaced grease, and should be removed when renewing grease.

4. The machine is capable of being run continuously while renewing grease. If the machine cannot be run continuously during the greasing period without injuring the driven auxiliary or endangering personnel, the bearing housing must be disassembled to renew grease.

If the above conditions apply, grease may be renewed in assembled bearing housings by the previously described greasing procedures.

Be careful to keep grease from reaching the electrical windings. The emergence of a large quantity of grease through the shaft extension end of the housing probably indicates excessive leakage inside the machine.

RENEWAL OF GREASE BY DISASSEMBLING THE BEARING HOUSING (THE PREFERRED METHOD).—The extent of disassembly necessary will depend upon the construction of the bearing. For the usual construction, (bearings with outer bearing caps), the following method should be used:

1. Remove the outer bearing cap after thoroughly wiping all exterior surfaces.

2. Remove old grease from all accessible portions of the housing and clean these parts thoroughly. Be careful not to introduce dirt or lint into the housing of bearing.

3. Flush out the bearing cap with clean hot (about 120° F.) kerosene, Diesel fuel oil, or dry-cleaning fluid (federal Specification P-S-661a). Follow this by flushing out with a light mineral oil (not heavier than SAE 10, similar to Diesel lubricating oil, symbol 9110).

4. Where practicable, plug all holes leading into the interior of the machine and flush out the complete housing with the outer bearing cap removed. Use the solvents and procedure described in the preceding paragraph. This should not be done where the conditions are such that the cleaning fluids may leak into the windings. In such cases, this step should be omitted.

5. Drain the mineral oil thoroughly; then pack housing half full with fresh, clean grease.

High Temperature Grease

Bearings which normally operate at a temperature above 194° F (90° C) should be lubricated with a silicone grease in accordance with Military Specification MIL-L-15719A, Stock No. W9150-257-5358. Machines which require this special grease have a caution plate stating "USE HIGH TEMPERATURE GREASE" which is attached near the grease fitting by the manufacturer.

Overheated Bearings

The temperature of sleeve bearings and the outer races of ball bearings should not be allowed to exceed the following values.

1. Sliding contact (sleeve) bearings 82° C (180° F).

2. Rolling contact (ball) bearings on class A or B insulated motors 90° C (194° F).

3. Rolling contact (ball) bearings on class H insulated motors 150° C (300° F).

The permissible operating temperature is too high to be estimated by sense of touch. Temperature measurements are needed to determine whether a bearing is overheated. A thermometer securely fastened to the bearing cover or housing will usually give satisfactory measurements. A thermometer should not be inserted into a bearing housing, it may break and necessitate disassembly to remove glass and mercury.

CORRECTIVE MAINTENANCE

DOUBLE SHIELDED OR DOUBLE SEALED BALL BEARINGS SHOULD NEVER BE DISASSEMBLED OR CLEANED. These bearings are prelubricated and cleaning will remove the lubricant from the bearings or at least dilute the lubricant until it no longer possesses its original lubricating qualities.

Permanently lubricated ball bearings require no greasing. Equipment furnished with these bearings can be recognized by the absence of grease fittings or provision for attaching grease fittings. When permanently lubricated bearings become inoperative, they should be replaced with bearings of the same kind. If not already provided, nameplates reading "DO NOT LUBRICATE" should be attached the bearing housings of machines with sealed bearings.

Open, single shielded, or single sealed ball bearings can be cleaned, but this should be done only in an emergency when a suitable replacement is not available. It is difficult to remove dirt from ball bearings. Unless carefully done, more dirt may get into the bearings than is removed.

11442

If cleaning an open, single shielded, or single sealed bearing is necessary, the bearing should be taken off the shaft with a bearing puller applied to the inner race of the bearing or to a sleeve which applies pressure to the inner race. Removal of bearings by pulling on the outer race tends to make the balls dent the raceway even if the puller is used. In instances where faulty operation has subjected the bearing to such extreme temperatures as to distort the race and balls and cause the race to shrink to the shaft more tightly than the original fit, care must be taken not to injure the shaft when removing the bearing.

After removal, the bearing should be thoroughly cleaned. A good cleaner to use is Stoddard solvent or clean oil. Soak the bearing in the cleaner for as long as necessary to dislodge dirt or caked grease from around balls and separators. After the bearing is cleaned, wipe it carefully with a dry, lint-free cloth. If compressed air is used for drying, direct the air stream across the bearing so that the bearing does not spin. Because dry bearings rust quickly, protect the bearing at once by coating it with clean, low-viscosity lubricating oil from an oil can.

Rotate the inner ring slowly by hand, and if the bearing feels rough, repeat the cleaning. If the bearing still feels rough when turned slowly by hand, it is not fit for use.

When installing either cleaned or new bearings, observe the precautions in chapter 9430, NavShips Technical Manual. Install double shielded or double sealed, cartridge type bearings as they are received because these are pre-lubricated. With open, single shielded, or single sealed bearings, however, the protective compound should be washed away, and the operating lubricant added to the bearing. Even after the bearings have been cleaned and inspected, the following points must be checked before actual bearing installation.

1. Shaft and housing diameters must conform to dimensional tolerances in the applicable specification.
2. Shaft and bearing seats must not be out-of-round or tapered.
3. Housings must be inspected for splits or cracks.
4. Shafts must be inspected for straightness.
5. Shaft and housing shoulders must be adequate and not out-of-square with the shaft.
6. Shafts, bearing housings, keyways, splines, etc., must be clean and lightly oiled.

There are four acceptable methods for mounting bearings.

1. Arbor press method. If available and adaptable, an arbor press can be used if proper precautions are taken. Place a pair of flat steel blocks under the inner ring or both rings of the bearing. Never place blocks under the outer ring only. Then line up the shaft vertically above the bearing, and place a soft pad between shaft and press ram. After making sure the shaft is started straight in the bearing, press the shaft into the bearing until the bearing is flush against the shaft or housing shoulder.

2. Infrared method. If a bearing is heated to expand the inner ring for assembly, heating can be done by the use of an infrared oven. The bearing should not be heated above 200° F. This method ensures uniform heating all around the bearing.

3. Oven method. Alternatively, bearings can be heated to expand the inner ring for assembly in a temperature controlled furnace at a temperature not to exceed 200° F. The bearing should not be left in the furnace beyond the time necessary to expand the inner race the desired amount, since heating for an excessive period of time would give rise to the possibility of deterioration of the grease with which the bearing is prelubricated.

4. Hot-oil method. A fourth method used in installing bearings is the hot-oil method which consists of heating the bearing in oil at 200° F until expanded and then slipping it on the shaft. This method is not desirable and should not be used unless absolutely necessary. The disadvantages of the hot oil method are:

1. The possibility of grease deterioration.
2. The possibility of bearing growth.
3. Inadequate or no temperature controls.
4. The possibility of contaminating the grease by use of dirty oil.

A most important point to be remembered and strictly followed is that when pressing a bearing onto a shaft, pressure must be applied to the inner ring, but when pressing a bearing into a housing, pressure must be applied to the outer ring.

Before the final assembly has been completed, the entire unit should be thoroughly checked for alignment.

The bearing should be packed with the proper lubricant and the cleaned bearing housing should be half filled with the same lubricant. The housing must be properly assembled and care must be exercised to prevent omission of bearing

11443

parts, lubricant seals, grease pipes, plugs, and fittings. These parts must be securely assembled to complete the housing closure and protect against the entrance of foreign materials. Bolts should be tightened evenly. Any "V" grooves in the housing lip should be filled with grease which will act as an additional seal to protect against entrance of dirt.

BRUSHES

The brushes used in electric motors and generators are one or more plates of carbon, bearing against a commutator, or collector ring (slip ring) to provide a passage for electrical current for an external circuit. The brushes are held in position by brush holders mounted on studs or brackets attached to the brush-mounting ring, or yoke. The brush holder studs or brackets, and brush-mounting ring comprise the brush rigging. The brush rigging is insulated from, but attached to, the frame of the machine. Flexible leads (pigtails) are used to connect the brushes to the terminals of the external circuit. An adjustable spring is generally provided to maintain proper pressure of the brush on the commutator in order to effect good commutation. A d-c generator brush holder and brush-rigging assembly are shown in figure 6-6.

Brushes are manufactured in different grades to meet the requirements of the varied types of service. The properties of resistance, ampere-carrying capacity, co-efficient of friction, and hardness of the brush are determined by the maximum allowable speed and load of the machine in which it is used.

CORRECT BRUSH TYPE

The correct grade of brush and correct brush adjustment are necessary to avoid commutation trouble.

Use the grade of brush shown on the drawing or in the technical manual applicable to the machine, except where Naval Ship Systems Command Instructions issued after the date of the drawing or technical manual (such as the instructions for brushes to be used in electric propulsion and magnetic minesweeping equipment) state otherwise. In such cases, the Naval Ship Systems Command Instructions should be followed. Most of the brushes in shipboard service are of a grade which has satisfactorily passed rigid tests at a Government laboratory and appear on the Qualified Products List as complying with one of six Military grades, S, A, H, D, G, and E. In the case of propulsion and magnetic minesweeping equipment, only one grade of each of two different brush manufacturers is permitted for any machine. This restriction on brush interchangeability is based on the vital nature of the machines involved and on the impracticability of factory testing these machines while operating with several manufacturers' grades which have been qualified under any one of the six military grades.

CARE

All brush shunts should be securely connected to the brushes and the brush holders.

Brushes should move freely in their holders but should not be loose enough to vibrate in the holder.

The following brushes should be replaced with new brushes, the replacement being preceded by cleaning all dirt and other foreign material from the brush holder.

1. Brushes which are worn or chipped to such an extent that they will not move properly in their holders.
2. Brushes which have damaged shunts, shunt connections, or hammer clips.
3. Brushes having riveted connections or hammer clips and are worn to within 1/8 inch of the metallic part.
4. Brushes having tamped connections and without hammer clips and worn to one-half or less of the original length of the brush.
5. Brushes having spring-enclosed shunts and worn to forty percent or less of the original length of the brush exclusive of the head which fits into one end of the spring.

Where brush springs are of the positive gradient (torsion, tension, or compression) type and are adjustable, they should be adjusted as the brushes wear, in order to keep the brush pressure approximately constant. Springs of the coiled band, constant pressure type and certain springs of the positive gradient type are not adjustable except by changing springs. Brush pressure should be in accordance with the manufacturer's technical manual. Pressures as low as 1 1/2 pounds per square inch of contact area may be specified for large machines and as high as 8 pounds per square inch of contact area may be specified for small machines. Where technical manuals are not available, a

158
11444

77.70

Figure 6-6.—Brush holder and brush-rigging assembly.

pressure of 2 to 2 1/2 pounds per square inch of contact area is recommended for integral horsepower and integral kilowatt machines, and about twice that pressure for fractional horsepower and fractional kilowatt machines. To measure the pressure of brushes operating in box type brush holders, insert one end of a strip of paper between the brush and commutator; use a small brush tension gage (such as the 0 to 5 pound indicating scale carried in General Stores under Stock No. GS6670-583-0063) to exert a pull on the brush in the direction of the brush holder axis as shown in fig. 6-7. Note the reading of the gage when the pull is just sufficient to release the strip of paper so that it can be pulled out from between the brush and commutator without offering resistance. This reading divided by the contact area may be considered to be the unit operating pressure. Taking correction factors into consideration, the actual pressure will be a few percent lower in the case of brushes operating in the leading position and a few percent higher in the case of brushes operating in the trailing position.

11445

77.72

Figure 6-7.—Measuring brush tension.

All brush holders should be the same distance from the commutator, not more than one-eighth inch, nor less than one-sixteenth inch.

The toes of all brushes on each brush stud should line up with each other and with the edge of one commutator segment.

The brushes should be evenly spaced around the commutator. To check brush spacing, wrap a strip of paper around the commutator and mark the paper where the paper laps. Remove the paper from the commutator, cut at the lap, and fold or mark the paper into as many equal parts as there are brush studs. Replace the paper on the commutator and adjust the brush holders so that the toes of the brushes are at the creases or marks.

Brushes should be staggered as shown by the correct method in figure 6-8A to prevent grooving of the commutator. The incorrect method of staggering, shown in figure 6-8B gives unsatisfactory results because the pitting effect is different under positive and negative brushes. For machines having a number of poles equal to two times an odd number, it will obviously not be possible to stagger all the brushes in accordance with the correct method. Stagger all but

77.71

Figure 6-8.—Method of staggering brushes.

the odd pair of positive and negative brushes in accordance with the correct method, and the odd pair in accordance with any two adjacent rows in the method of figure 6-8B.

SETTING ON NEUTRAL

When a machine is running without load and with only the main-pole field windings excited, the point on the commutator at which minimum voltage is induced between adjacent commutator bars is the no-load neutral point. This is the best operating position of the brushes on most commutating-pole machines. Usually, the brush studs are doweled in the proper position, and the correct setting is indicated on a stationary part of the machine by a chisel mark or an arrow. In some cases, commutation may be improved by shifting the brushes slightly from the marked position.

The correct neutral position can be found by the use of:

(a) The mechanical method.
(b) The reversed rotation method.
(c) The inductive kick method.

The mechanical method is an approximate method. Turn the armature until the two coil sides of the SAME armature coil are equidistant from the center line of one MAIN field pole. The commutator bars to which the coil is connected give the position of the mechanical neutral.

Use of the reversed rotation method is possible only where it is practicable to run a machine

11446

Figure 17-27. —PPI sweep circuit, simplified schematic.

is developed in the plate winding of V15 and a voltage is induced in the secondary. This voltage will cause a square wave of current in the secondary, in the opposite direction to the sawtooth of current. The square wave must be developed at the end of the sweep time. V13 is cut off with a positive voltage on its cathode. The positive voltage to cut off V13 is developed by driving V11 into conduction. V11 is driven into hard conduction by the positive-going voltage from the plate of V12, when V12 is cut off. V12 is cut off by a negative pulse from a single-cycle blocking oscillator, V10. V11 and V12, with associated parts, constitute a free-running multivibrator. The time that V11 is conducting is equal to the time that V12 is cut off. This time is controlled by the setting of R17. R17 is adjusted for the proper compensation. If the arm of R17 is moved up, the time duration of the compensation gate will increase. Too much compensation results in an open-center presentation on the scope.

To insure that the compensation gate is generated at the end of the sweep, a square wave of voltage is taken from the cathode of V2; the negative portion of the square wave occurs during sweep time. The square wave is differentiated by the coupling capacitor C4 and R14. At the end of sweep time, a positive pulse will trigger V10 and a negative pulse is coupled from the bottom of R15 through C5 and C6 to the grid of V12. This pulse will synchronize the free-running multivibrator (V11 and V12). Therefore, the compensating gate always occurs at the end of sweep time.

MARKER CIRCUITS

Marker circuits consist primarily of range marks (fixed and variable), an azimuth marker, and a marker-mixer circuit.

AA 1142

in either direction of rotation, with rated load applied. This method differs for motors and generators. For motors, the speed of the motor is, at first, accurately measured when the field current becomes constant under full load at line voltage with the motor running in the normal direction. Then, the rotation of the motor is reversed, full load is applied, and the speed is again measured. When the brushes are shifted so that the speed of the motor is the same in both directions, the brushes will be in the neutral position. Generators are run at the same field strength and same speed in both directions, and the brushes are shifted until the full-load terminal voltage is the same for both directions of rotation. To ensure accuracy, a reliable tachometer must be used to measure the speed of the machines for this method.

The kick method should be used only when the other methods are inadequate and the conditions are such as to warrant the risks involved, and then only when sufficient resistance is connected in series with the field coils to reduce the field current to approximately 10 percent of normal value.

The rapid interruption of full field current induces voltages which are dangerous to personnel and which may cause the breakdown of insulation. With a lead pencil or other means that will not damage the surface, mark A on a commutator bar under one set of brushes. Mark B on another bar one pole pitch away from the center of the bar marked A. A pole pitch is the angular distance from the center of one main pole to the center of the next main pole. Raise all brushes. Connect bars A and B to a low range voltmeter having two or three scales (for example, 0-0.5, 0-1.5, 0-15 volts). Use leads with pointed prongs to connect the bars. Separately excite the shunt field winding from a d-c source connected to the winding in series with a high resistance and a quick-break switch. Start with the minimum obtainable value of field current and the high range scale of the voltmeter.

Close the knife switch, wait for the momentary deflection to disappear, open the knife switch, and note the momentary deflection or kick of the voltmeter. If insufficient deflection is observed on the lowest range scale of the voltmeter, decrease the resistance connected in series with the shunt field winding and repeat the procedure until an adequate deflection is obtained on the voltmeter when the switch is opened. Retain this setting of the resistor for remainder of the test. Turn the armature slightly until the position is found at which the minimum kick is produced when the field current is broken. Bars A and B will then be on neutral. If one pole pitch from the center of bar A does not fall on a bar, but on the mica between two bars, mark the bars next to the mica, C and D. Then measure the kick when bar A and bar C are connected to the voltmeter, and again when A and D are connected to the voltmeter. Adjust the position of the armature until these two deflections are equal and opposite. The center line of bar A and the mica between bars C and D will then be on neutral.

SEATING

Accurate seating of the brushes must be assured where their surfaces contact the commutator. Sandpaper and a brush seater are the best tools to accomplish a true seat.

All power must be disconnected from the machine, and every precaution must be taken to ensure that the machine will not be inadvertently started before using sandpaper to seat the brushes. The brushes to be fitted are lifted, and a strip of fine sandpaper (No. 1) approximately the width of the commutator, is inserted (sand side up) between the brushes and the commutator. With the sandpaper held tightly against the commutator surface to conform with the curvature and the brushes held down by normal spring pressure, the sandpaper is pulled in the direction of normal rotation of the machine (fig. 6-9).

1.52

Figure 6-9.—Method of sanding brushes.

841447

When returning the sandpaper for another pull, the brushes must be lifted. This operation is repeated until the seat of the brush is accurate. Always finish with a finer grade of sandpaper, No. 0. A vacuum is required for removing dust while sanding. After sanding, the commutator and windings must be thoroughly cleaned to remove all carbon dust.

The brush seater is compounded of a mildly abrasive material loosely bonded, and is formed in the shape of a stick about 5 inches in length. The brush seater is applied to the commutator while the machine is running, and every precaution should be taken to prevent injury to the person applying it. The brush seater is touched lightly, for a second or two, exactly at the heel of each brush (fig. 6-10). If placed even one-fourth inch away from the heel, only a small part of the abrasive will pass under the brush. Pressure may be applied to the brush by setting the brush spring tension at maximum or by pressing a stick of insulating material against the brush. The dust is removed during the operation, and the machine is thoroughly cleaned afterwards in the same manner as for sanding brushes.

1.53

Figure 6-10.—Using the brush seater.

COMMUTATORS AND COLLECTOR RINGS

After being used approximately two weeks, the commutator of a machine should develop a uniform, glazed, dark brown color on the places where the brushes ride. If a nonuniform or bluish colored surface appears, improper commutation conditions are indicated. Periodic inspections and proper cleaning practices will keep commutator and collector-ring troubles at a minimum.

CLEANING

One of the most effective ways of cleaning the commutator or collector rings is to apply a canvas wiper while the machine is running. The wiper can be made by wrapping several layers of closely woven canvas over the end of a strong stick between one-fourth and three-eighths inch thick (fig. 6-11). The canvas may be secured with rivets if they, in turn, are covered with linen tape to prevent the possibility of their contacting the commutator. When the outer layer of canvas becomes worn or dirty, it is removed to expose a clean layer. The wiper is most effective when used frequently. On ship's service generators, it may be desirable to use the wiper once each watch. When using the wiper, exercise care to keep from fouling moving parts of the machine. The manner of applying the wiper to a commutator is illustrated in figure 6-12.

When machines are secured, a toothbrush can be used to clean out the commutator slots, and clean canvas or lintless cloth may be used for wiping the commutator and adjacent parts.

1.54.1

Figure 6-11.—Canvas wiper.

1.54.2

Figure 6-12.—Using the canvas wiper on a commutator.

In addition to being cleaned by wiping, the commutator should be periodically cleaned with a vacuum cleaner or blown out with clean, dry air.

A fine grade of sandpaper, No. 00, may be used to clean a commutator that is only slightly rough, but not out of true. Sandpapering is recommended for reducing high mica, and for finishing a commutator that has been ground or turned. The sandpaper, attached to a wooden block shaped to fit the curvature of the commutator, is moved slowly back and forth across the surface of the commutator while the machine is running at moderate speed. Rapid movement or the use of coarse sandpaper will cause scratches. Emery cloth, emery paper, or emery stone should never be used on a commutator or collector ring.

CARE OF COMMUTATORS

Commutators must be true within close limits. For the most satisfactory operation, runout (eccentricity) of the commutator surface (as checked on the radius with an indicator) should not exceed two mils (0.002 inch). Handstoning, grinding with a rigidly supported stone, and turning the commutator are measures that will correct some or all out-of-true conditions of the commutator.

For handstoning, the machine should be running at, or only slightly below, rated speed. For motors, remove all except enough brushes to keep the armature turning at the proper speed. The stone to be used should fit the curvature of the commutator and have a surface substantially larger than the largest flat spot to be removed. Hold the stone in the hand and move it very slowly back and forth, parallel to the axis of the commutator, applying only enough pressure to keep the stone cutting (fig. 6-13). Crowding the stone will roughen the surface. Care must be exercised to avoid electric shock and to prevent jamming the stone between fixed and moving parts of the machine.

Either a nonrotating or a revolving stone can be used when grinding the commutator with a rigidly supported stone (fig. 6-14). Irrespective of which stone is used or whether the grinding is done with the commutator within the machine or in a lathe, extreme care must be taken to align the supports so that the motion of the stone is accurately parallel to the axis of the commutator. Failure to properly align the supports will taper the commutator, and failure to maintain the support rigid will cause the stone to dig into the commutator.

For turning, the armature should be supported in a lathe (fig. 6-15). A cutting tool that is rounded sufficiently so that the cuts will overlap must be used to make the cut. Proper cutting speed is about 100 feet per minute with the feed about 0.010 inch per revolution. Depth of the cut should not exceed 0.010 inch.

The windings of the machine must be adequately protected from grit during stoning and grinding operations conducted with the commutator in the machine. Afterwards, the brushes, brush holders, and commutator must be thoroughly cleaned, and a complete insulation test should be made to determine that no grounds or short circuits exist. After the truing-up operation has been completed, regardless of the method used, always finish with a fine grade of sandpaper, undercut the mica to a depth no greater than one-sixteenth inch, and slightly bevel the edges of the commutator bars.

When the oxide film (dark brown color) has been removed by truing operations, it can be replaced by burnishing the commutator with a hardwood block. After the end grain of the block has been shaped to the curvature of the armature, the block is pressed hard against the surface of the commutator while the machine is running. A commercial burnishing stone may also be used for this purpose. Less pressure is required in applying the stone because friction is greater, and the heat developed is high. Do not raise the commutator temperature above its normal operating level.

Commutator mica that has become carbonized loses its insulating value. The carbonized portion should be scraped out and replaced with sodium silicate or other insulating cement. Poor commutation will develop if the commutator bars are worn down to, or below, the level of the mica. The mica should be undercut to a depth of between three sixty-fourths inch and one-sixteenth inch below the level of the commutator bars. A small motor-driven, circular saw especially designed for this purpose, a slotting file having an angle of 60° between faces, or a hacksaw blade that has been ground to the right thickness and fitted to a handle may be used for undercutting mica. Before using the motor-driven circular saw, install a canvas cover around the armature in a manner to prevent copper dust from becoming embedded in the armature windings. When undercutting has been

11449

73.161

Figure 6-13.—Handstoning the commutator.

completed, the edges of the bars should be beveled to a depth about one thirty-second inch below the surface. Finally, all mica, copper dust, and other foreign materials must be cleaned from the slots and commutator.

CARE OF COLLECTOR RINGS

Collector rings (slip rings) require the same careful attention as the commutator. Out-of-round conditions of the rings may be corrected in the same manner as for commutators, except for the fact that crocus cloth is used to apply a mirror-like finish following any turning, grinding, or sanding operations.

Pitting can develop because of the electrolytic action on the surface of collector rings caused by current flow. It may occur in only one ring, but will be general over the whole ring area. This condition can be corrected by reversing the polarity of the rings every few days. Reversing the polarity of the a-c field of a 3-phase generator will not affect the phase rotation of the generator.

Field current must not be left on while a machine is secured because it will cause spot pitting and burning of the rings beneath the brushes.

11450

77.73

Figure 6-14.—Grinding the commutator with a rigidly supported stone.

ARMATURES

Preventive maintenance of an armature consists of periodic inspections and tests to determine its condition, and proper cleaning practices to preserve the insulation.

Frequent checks must be made of the condition of the banding wire that holds down the windings of the d-c armature to see that the wires are tight, undamaged, and have not shifted (fig. 6-16). At the same time, the clips securing the wires should be checked to see if solder has loosened. When repairs are required, banding-wire size, material, and the method of original assembly should be duplicated as far as possible. Only pure tin must be used for soldering banding wire.

Periodically, all end windings should be inspected and cleaned (fig. 6-16). Allow sufficient clearance between the end windings and end brackets or any air deflecting shields to prevent chafing or other damage. In cases where shop overhaul is not feasible, air-drying varnish may be applied to the windings by brush after they have been cleaned and dried.

Risers must be inspected periodically to determine the condition of the solder that secures the windings to the segments (fig. 6-16). All dirt

11451

77.74

Figure 6-15.—Truing commutator by turning.

5.143

Figure 6-16.—D-c armature.

and lint should be removed by thorough cleaning to ensure that cooling passages will not be clogged. It may be necessary in the case of generators to do this each time the machine is secured. Cleaning is easier when performed while the machine is warm.

TROUBLE INDICATIONS

Some armature troubles may be detected while making inspections of running machines. Heat and the odor of burning insulation may indicate a short-circuited armature coil. In a coil that has some turns shorted, the resistance of one turn of the coil will be very low, and the voltage generated in that turn will cause a high-current flow, resulting in excessive heating, which will cause the insulation to burn. If the armature is readily accessible, the short-circuited coil can be detected immediately after stopping the machine because the shorted coil will be much hotter than the others. In idle machines, a short-circuited coil may be identified by the presence of charred insulation.

An open armature coil in a running machine is indicated by a bright spark, which appears to pass completely around the commutator. When the segment to which the coil is connected passes under the brushes, the brushes momentarily complete the circuit; when the segment leaves the brushes, the circuit is broken, causing a spark to jump the gap. Eventually, it will definitely locate itself by scarring the commutator segment to which one end of the open coil is connected.

When a ground occurs in an armature coil of a running machine, it will cause the ground test lamps on the main switchboard to flicker on and off as the grounded coil segment passes from brush to brush during rotation of the armature. Two grounded coils result in the same effect as a short circuit across a group of coils. Overheating will occur in all of the coils in the group and burn out the winding. Grounded coils in idle machines can be detected by measuring insulation resistance. A megger, or similar insulation measuring device can be connected to the commutator and to the shaft or frame of the machine in order to properly measure the resistance of the insulation of the coils.

LOCATING TROUBLES

D-c armature troubles are usually confined to one coil or group of coils, and if not readily apparent, the segments to which they are connected can be located by a bar-to-bar test. In some cases, this test may be conducted with the armature installed in the machine. A low-voltage, d-c source, such as a storage battery, lighting circuit, or welding set, is required for this test. The machine must be disconnected from its normal power supply before the test is made and all except one pair of brushes lifted from the commutator. The voltage is applied across the + and - brush through a resistance, lamp, lamp bank, or rheostat. A low-reading voltmeter or millivoltmeter is necessary for taking measurements.

To locate a ground in a d-c armature coil, one lead of the voltmeter is connected to the shaft, and, with the armature in a fixed position, the other lead is touched to each commutator bar in turn. If there is a ground, two or more bars will indicate practically zero readings. Some of these will be real and others will be phantom grounds (fig. 6-17 A). All such bars should be marked with chalk. The armature is then rotated a few degrees and tested again. The real grounds will remain in the same bars while the phantom ones will shift to other bars (fig. 6-17 B). For example, in figure 6-17 B, the phantom ground has shifted from bar b to bar c, while the real ground has remained in bar a. The ground will be in a coil connected to the bar, showing a real ground with the lowest voltage reading.

To locate an open or short circuit in a d-c armature, remove all brushes except those of one positive brush holder and an adjacent negative brush holder. Connect the low-voltage potential to these brushes and adjust the current, if need be, so that the readings obtained with the millivoltmeter will be roughly one-third to one-half full scale. The current must not exceed one-fourth that normally carried by one set of brushes. The voltage drop between two adjacent commutator bars is measured with a millivoltmeter. The armature is held in a fixed position, and the meter leads are moved from one pair of adjacent bars to the next until a test has been made of all the pairs of bars included between the brushes (fig. 6-18). The armature is then turned to bring different bars between the brushes, and these bars are tested. This is repeated as necessary to test all around the commutator. In a simplex winding, an open coil is located where the meter reading is a maximum, and a shorted coil where the reading is a minimum.

For most armatures in use aboard naval vessels, the windings will be free from fault if all the voltage readings are a small fraction of the voltage between the brushes and are equal within the limits of measurement. However, in some cases, a duplex winding may be encountered. This type of winding is indicated when the readings are only a small fraction of the voltage between the brushes and follow each other in a regularly repeating pattern, such as O, R, O,R,O,R, and so on, where R is a reading different from zero. When this happens, a further test must be made by measuring the voltage drop between alternate bars—1 and 3, 2 and 4, 3 and 5, 4 and 6, and so on. If these readings are

77.75

Figure 6-17.—Real and phantom grounds in bar-to-bar test.

77.76

Figure 6-18.—Testing for an open coil.

equal within the limits of measurement, the winding will be free from faults.

When an open circuit is present, the voltmeter reading across one pair of adjacent bars will be approximately equal to the voltage between the brushes, and zero readings will be obtained on several pairs of bars on each side of the pair with the high reading. The open-circuited coil will be connected to one or both of the bars in the pair with the high reading. Should the voltmeter readings taken between adjacent pairs of bars increase or decrease in magnitude and be alternately plus and minus, a duplex winding is indicated. A further test by measuring the voltage drop between alternate bars is then necessary to locate the open circuit. When a reading approximating the voltage between the brushes is thus obtained, the open-circuited coil will be connected to one or both of the bars in the pair with the high reading.

When a short circuit is present, the interpretation of the indication given by readings between adjacent bars or between alternate bars (duplex windings) depends upon whether the

11453

armature has a lap or a wave winding. In an armature having a lap winding, a voltmeter reading considerably lower than the others will indicate a short-circuited coil is connected between the pair of bars that shows the low reading. A short-circuited coil in an armature with a wave winding will cause low readings to be obtained on as many pairs of bars as there are pairs of poles, and the short circuit will be in a coil connected to bars in these pairs.

The best method for locating the ends of a faulty coil in a wave-wound armature is to separate the coil from the rest of the winding in the following manner. In a six-pole machine, a short-circuited coil in a wave-wound armature would be indicated at three positions during the test. These positions should be marked with chalk. When the riser connections on these segments are lifted, six coils will be isolated from each other and the rest of the winding. The shorted coil is located by comparing the resistances of the six coils, and it will have less resistance than the others.

Emergency repairs can be effected by cutting out a short-circuited or open-circuited armature coil. This will permit restoration of the machine to service until permanent repairs can be made. However, permanent repairs should be made as soon as possible. The coil is cut out by disconnecting both ends of the coil and installing a jumper between the two risers from which the coil was disconnected. The coil itself is then cut at both the front and rear of the armature to prevent overheating of the damaged coil. A continuity test from one end to the back of the coil will locate the turns of the faulty coil. If a pin or needle is used to puncture the insulation for this test, insulating varnish can be used to fill the tiny hole in the event the wrong coil is pierced. All conducting surfaces exposed by the change in connections should be insulated and all loose ends should be tied securely to prevent vibration.

A-C ROTORS

Basically, the rotors in a-c motors are of two types - the squirrel cage rotor (fig. 6-19) and the wound rotor. The squirrel cage rotor usually consists of heavy copper or aluminum bars fitted into slots in the rotor frame. These bars are connected to short-circuiting end rings by being cast or brazed or welded together (fig. 6-19 A). In many cases, the cage rotor is manufactured by die-casting the rotor bars, end rings, and cooling fans into one piece (fig. 6-19 B). The cage rotor requires less attention than the wound rotor. However, the cage rotor should be kept clean, and the rotor bars must be checked periodically for evidence of loose or fractured bars and localized overheating.

A - WELDED ROTOR BARS AND END RINGS

B - DIE-CAST ROTOR BARS AND END RINGS

77.77

Figure 6-19.—Cage rotor.

In the wound rotor, the uninsulated bar winding of the cage rotor is replaced with a distributed winding of preformed coils similar to those of a d-c armature. The windings are wye-connected and the ends are brought out to collector rings (fig. 6-20). Wound rotors, like other windings, require periodic inspections, tests, and cleaning. The insulation resistance determine if grounds are present.

An open circuit in a wound rotor may cause reduced torque accompanied by a growling noise, or failure to start under load. In addition to reduced torque, a short circuit in the rotor windings may cause excessive vibration, sparking at the brushes, and uneven collector ring wear. With the brushes removed from the collector rings, a continuity check of the rotor coils will reveal the presence of a faulty coil. Emergency repair of a faulty coil in a wound rotor

11454

77.78

Figure 6-20.—Wound rotor.

may be effected in the same manner previously prescribed for cutting out a damaged armature coil.

Capacitors used with single-phase motors for starting should be checked by means of a capacity tester. This also applies to the capacitor-start capacitor-run type capacitors.

Some single-phase, a-c motors, such as the split-phase motor, are equipped with a centrifugal switch mounted on the rotor or rotor shaft. This device functions to open the starting winding circuit when the motor has reached almost normal speed. The condition of the device must be checked periodically to determine that the switch contacts are clean and that all moving parts function properly. Stalling while starting or failure to start may indicate a faulty centrifugal switch. If this happens, power to the motor must be secured immediately or the starting winding will soon overheat and burn out.

FIELD COILS

Preventive maintenance of field coils requires periodic inspections and tests to determine the condition of the coil. Coils should be cleaned periodically to remove any foreign particles, which might have collected on them.

LOCATING TROUBLES

The insulation on field coils should be tested periodically to determine its condition. A megger or similar resistance-measuring device may be used for this purpose. If a ground is detected in the field circuits (shunt, series, and interpole) of a d-c machine, the circuits must be disconnected from each other and tested separately to locate the grounded circuit. Then all the coils in that circuit must be opened and tested separately to locate the grounded coil, which can be repaired or replaced as necessary.

If an open circuit develops in the field windings of an a-c or d-c generator that is carrying load, it will be indicated by immediate loss of load and voltage. An open in the shunt field winding of an operating d-c motor may be indicated by an increase in motor speed, excessive armature current, heavy sparking, or stalling of the motor. When an open occurs in the field circuit of a machine, it must be secured immediately and examined to locate the faulty circuit. The open circuit will usually occur at the connections between the coils and can be detected by visual inspection. An open in the coils generally causes enough damage to permit detection by visual inspection. If the faulty coil is not readily apparent, it can be located by applying a low-voltage source (dry batteries) to the terminals of the field winding and using a low-range voltmeter to measure the difference of potential between the terminals of each coil (fig. 6-21). The open-circuited coil will develop the greatest difference in potential between its terminals.

77.79

Figure 6-21.—Testing for an open-circuited field coil.

11455

A short-circuited field coil in a machine develops an unbalanced magnetic pull and causes vibration. If the short circuit is severe, smoke or the odor of burning insulation will be present. In a generator, a shorted field coil is indicated when it becomes necessary to increase field current in order to maintain voltage with the machine running at normal speed. A machine with a shorted field coil must be secured immediately. The faulty coil can be located by passing normal current through the field circuit and measuring the voltage drop across each coil. The coil indicating the lowest voltage will be the shorted coil.

REPLACING COILS

A field coil may be removed from a large machine without removing the armature. However, the armature should be covered with heavy paper or canvas to prevent damaging it while the coil is being removed. To remove the coil, the field windings are disconnected, and then the bolts securing the pole piece to the frame are removed. The coil and pole piece can be slid from the machine intact. Care must be taken not to lose or misplace any of the shims found on the pole piece.

Before installing a new or repaired coil, its polarity must be determined and it should be tested for shorts, opens, and grounds. A small magnetic compass may be used to determine the polarity of a field coil. A small battery is connected to the coil leads, and the compass points toward the center of the coil, the face of the coil nearest the compass will be a north pole. This will indicate that the coil should be placed on a north pole in the same position it was in during the test, and the field current should flow through the coil in the same direction.

To protect the armature, the same precautions that were observed during removal of the coil must be observed when installing it. All of the shims originally removed from the pole piece must be in position when it is replaced. With the coil in position in the machine, it should be temporarily connected to the other coils in the field circuit and a compass and battery again used to check its polarity. For this test, connect the battery to the proper field leads and check the polarity of all the coils with the compass (fig. 6-22). Adjacent poles must be of opposite polarity. If need be, polarity of the new coil can be reversed by reversing its leads. When the polarity is correct, the coil is connected, and the pole-piece bolts are tightened. Air gaps should be measured to ensure uniformity. Before starting the machine, test it thoroughly to ascertain that no grounds, shorts, or opens exist as a result of the repairs.

77.80

Figure 6-22.—Testing polarity of field coils.

REWINDING FIELD COILS

Review all available information concerning the machine before rewinding a field coil. This includes reviewing the material history card (NavShips 527A), the resistance test card (NavShips 531), the master drawings, and technical manuals. The old field coil is removed from the pole piece and, if spare coils are available, a new one is installed. If a new coil must be made, record all pertinent coil data as the old coil is stripped down.

This data should include the (1) dimensions of the coil, both with the tape on and with the tape removed, (2) weight of the coil without the tape, (3) size of wire, and (4) type of insulation.

The two general classes of coils are (1) shunt field coils, which consist of many turns of fine wire and (2) series and commutating field coils, which consist of fewer turns of heavy wire. For coils of comparatively few turns, it is essential that exactly the same number of turns of wire are rewound on the coil as were contained in the original coil.

11455

11456

The primary function of the range marker circuit is to provide range markers to be used in determining range to targets. It also supplies a gating pulse to the intensity gate circuit on normal operation. It consists of a range marker gate, range marker gate cathode follower, range marker switch, range marker oscillator, range marker squaring amplifier, and the final amplifying and shaping circuit called the range marker generator. The output of the range marks are fed to a marker mixer.

The discussion of range marker circuits is contained in chapter 16 of this course.

The azimuth marker is a line produced once each scan to provide the operator with the necessary bearing information. The azimuth-marker circuit generates the electrical pulses which appear as azimuth markers. However, these pulses are not fed directly to the indicators but are fed through the marker-mixer circuit where they are combined with other markers.

The inputs to the marker-mixer circuit are range marks from the range marker circuits and azimuth markers. The function of this circuit is to further amplify these markers before they are fed to the indicators.

Azimuth Marker

The azimuth-marker synchro in the antenna is excited by the azimuth-marker exciter, which is a Hartley type oscillator whose 4000-cycle sine-wave output is applied across the rotor of the azimuth-marker synchro. The rotor of the azimuth-marker synchro, in any position, induces in the stator a 4000-cycle voltage. This voltage varies in amplitude in a sinusoidal manner from zero to maximum in each 180° of rotation of the antenna. The 4000-cycle voltage is then applied to the stator of the differential synchro in the antenna control. The voltage induced in the rotor of the differential synchro is shown in figure 17-28.

The output of the differential synchro is connected to two grid limiters which limits the 4000-cps voltage until it appears as shown in figure 17-29. This action causes the nulls at 180° and 360° to be very narrow.

Consider the static condition of V149 and V151 in figure 17-30 before the arrival of the signal at the grid of V149. The bleeder network R291, R292, and R293 places a bias voltage on the grid of V149, which causes this grid to be at or very near cutoff. The voltage divider R295,

Figure 17-28.—Azimuth-marker exciter output.

R296, and R297 places the grid of V151 at or near zero bias; in this condition, it will oscillate. Therefore, in the rest or static condition, we may consider V149 cut off and V151 oscillating. When the envelope of 4000-cycle voltage is applied to the grid of V149, it will conduct on the positive half of each 4000-cycle alternation. As V149 conducts, its plate voltage is lowered and C187 and C188 assume a d-c average charge corresponding to the average voltage at the plate of V149. This voltage drop lowers the potential at the junction between R296 and R298 and also lowers the voltage at the grid of V151 so that it will not oscillate. Therefore, when a signal is present that will drive the grid of V149 far enough in a positive direction, V151 is biased far enough negative so that there is no output. When the signal drops to zero or into a null point, the grid of V149 goes to cutoff and no plate current is drawn. The grid of V151 will be driven to or near zero potential and V151 will oscillate, causing a marker on the scope. It is obvious that the mark will only be seen during a null, and a relay is provided to eliminate the unwanted null.

Figure 17-29.—Azimuth-marker differential synchro output.

1143

The exact number of turns in a shunt coil having many turns of fine wire is not especially important. A slight error would be a very small percentage of the total. The number of turns in a shunt coil can be determined by mounting the defective coil on a lathe face plate, which is attached to a revolution counter, and counting the number of turns as the coil is unwound.

SHUNT COILS.—The equipment for rewinding shunt coils includes a lathe or suitable face plate, which can be turned at any desired speed, and an adequate supply of the proper size wire wound on a spool, which can be supported on a shaft so that it is free to turn. Friction should be applied to the spool to provide tension on the wire. A coil form having the exact inside dimensions of the coil is secured to the lathe or face plate. The form for shaped field coils can be made from a block of wood shaped exactly to the required size and provided with flanged ends to hold the wire in place (fig. 6-23). One of the flanges should be removable so that the finished coil can be taken from the forming block.

77.81

Figure 6-23.—Coil form for field coils.

The wire is now wound from the spool onto the forming block for the required number of turns. The turns must be evenly spaced, one against the other, until the winding procedure is completed. The turns of the completed coil are secured by tape, and the wire leading to the spool is cut, leaving sufficient length to make the external connections.

The inside lead is led across the coil side, and a piece of fish paper is inserted between the lead and the coil to provide insulation. The inner and outer leads are insulated from the coil with cotton or reinforced mica tape and are secured with tape or cord to prevent shifting (fig. 6-24). The terminal leads are usually heavier than the coil ends and consist of stranded wire, which must have a good soldered connection that is electrically and mechanically secure.

77.82

Figure 6-24.—Rewound shunt coil.

The coil end is doubled back to form a loop, thus increasing its mechanical strength before soldering to the terminal lead. The binder insulation consisting of cotton or glass tape (class A or class B insulation) is applied to the entire coil surface, and the shape of the coil is carefully preserved. The completed coil must be checked electrically for continuity and for shorted turns.

The coil is now prebaked and varnish treated. When varnish treated, the finished field coil should withstand a high-potential test of twice the rated excitation voltage +1,000 volts.

If it is necessary to shape the field coil to fit the inside curvature of the machine frame, it should be bent into shape before applying the varnish. A satisfactory method of bending the field coils is to make a wooden form having two parts that are properly curved. The coil is placed between the two parts and pressed into the required curvature.

SERIES AND COMMUTATING COILS.—Series and commutating field coils are frequently wound with strap (rectangular) or ribbon copper instead of round wire. These coils have only a

few turns that are wound in a single turn per layer. A strap-wound series coil is illustrated in figure 6-25.

A series coil wound (with ribbon copper) on edge is illustrated in figure 6-26. It is more difficult to bend the copper ribbon, but it has an advantage in that both terminal leads protrude on opposite sides of the coil. Thus, the connections can be made very easily compared to the strap-wound coils, which have one coil end at the center and the other coil end at the outside of the coil. The strap-wound construction requires leading the inside coil end over the turns of strap in the coil.

Strap-wound and edge-wound coils are usually provided with a single layer of varnished cambric between the turns, and the entire coil surface is wound with cotton or glass tape (class A or class B insulation). Heavy banding wire well insulated from the turns is usually necessary to retain the ribbon copper turns in place. After the winding is completed, the coil is tested electrically for continuity and shorted turns. It is then prebaked and varnished.

77.83

Figure 6-25.—Strap wound series coil.

77.84

Figure 6-26.—Edge-wound series coil.

The completed coil must be tested (fig.6-22) for polarity, grounds, opens, and shorts. The polarity test automatically indicates whether or not the coil has an open.

The current should be sent through all the field coils in series (to test for a short), and the voltage drop measured across each coil separately. The new coil should have about the same voltage drop as the other coils. However, if the voltage drop is less than the other coils, the new coil has too few turns or it has been wound with wire that is too large. The growler can also be used as a quick check for shorts.

A-C STATOR COILS

A-c stator windings require the same careful attention as other electrical windings. For a machine to function properly, the stator windings must be free from grounds, short circuits, and open circuits. Frequent tests and inspections are necessary to determine the condition of the windings, and they must be kept clean to preserve the insulation.

A short circuit in the stator of an a-c machine will produce smoke, flame, or the odor of charred insulation. The machine must be secured immediately; the faulty coil may be located if the coil ends are felt before they have time to cool. The shorted coil ends will feel perceptibly hotter than those adjacent to it. Emergency repairs of a faulty stator coil may be effected by cutting it out in the same manner as cutting out a faulty armature coil. However, a new coil must be installed as soon as possible.

Open circuits in a-c stator windings can sometimes be found by visual inspection because the open is usually the result of damaged connections where the coils and circuits are connected together. Should visual inspection fail, resistance measurements between the phase terminals will reveal the presence of open-circuited coils. The coil ends in the faulty phase are tested with an ohmmeter to locate the open-circuited coil. When the open circuit is in an

11458

maintenance schedule should be prepared and maintained. To be effective, the checkoff list must identify the equipment and indicate when and by whom the maintenance was accomplished. The list should be inspected periodically by the Electrical Officer or Engineer Officer, and when applicable, entries to the effect that certain maintenance has or has not been performed should be made in the appropriate electrical history, current ships maintenance project, or operating logs.

It may not be possible to carry out a complete maintenance schedule on some shipboard equipment because of its inaccessible location. However, the Naval Ship Systems Command required maintenance schedule for motors and generators which follows, should be carried out so far as practicable, and if experience or manufacturer's instructions dictate, should be supplemented by additional or more frequent tests and inspections.

DAILY

1. Check oil level and condition of oil rings in oil-lubricated bearings, and the flow of oil (by sight gage) in force-feed lubricated bearings.
2. Inspect motor and generator surroundings for dripping water, oil, steam, acid, excessive dirt, dust, or chips, and any loose gear that might interfere with ventilation or jam moving parts.
3. Observe running motors for vibration and unusual or excessive noise.
4. Examine each running generator set for cleanliness, vibration, unusual or excessive noise, heating; and condition of brushes, commutators, collector rings, bearings, bolts, and mechanical fastenings.

WEEKLY

1. Check temperatures of bearings and frames. Estimate by touch, and if temperature appears to be excessive, measure with a thermometer.
2. Inspect for leakage of lubricant from generator and motor bearings, as shown by oil or grease on the shaft extension or lubricant creeping towards the winding.
3. Inspect for leakage of lubricant from the bearings of prime movers that drive generators.
4. Inspect commutators of idle machines for commutator condition.
5. Inspect collector rings of idle machines for evidence of corrosion.
6. Inspect all running motor for unusual sparking.
7. Run each generator at partial or full load for at least 30 minutes once a week, and record in log. If it is not practicable to run each set every week because of naval shipyard work, extensive overhaul, or casualty, an entry shall be made in the log stating the facts.
8. Blow out generators that have been in use with clean, dry, compressed air, and wipe with a lintless cloth.
9. Measure the insulation resistance of generators and excitation circuits.

Figure 6-28 is a representative maintenance requirement card which covers the cleaning and insulation resistance readings as required weekly on an emergency generator. Note however, the Maintenance Requirement Card does not include the weekly load testing of the generator, but lists only the minimum required maintenance.

Keep in mind the fact that completion of the requirements as shown on the MRC cards does not cover all of the tests and inspections which are required on your equipment.

MONTHLY

1. Run each generator continuously for at least 4 hours once a month at full-rated load and voltage. Record in log. If it is not practicable to apply full load, the maximum load possible should be used, and an entry should be made in the log, giving the load used, and the reason why full load was not practicable. If it is not practicable to run each generator for this test every month, an entry should be made in the log stating the facts.
2. Inspect the zincs in motors and generators equipped with air coolers.
3. Remove the drain plugs provided in Navy Class A spraytight, watertight, and submersible motor enclosures to drain off water that may have collected in the enclosures. Be sure to replace the drain plugs immediately after draining the motor enclosures. The draining of the motor enclosures should be entered in the log or electrical history, as appropriate, together with an entry giving a rough idea of the amount of water drained off.
4. If operating conditions permit, measure the insulation resistance of each ship's service and emergency generator and exciter, and of

M. R. DESCRIPTION

1. Clean the generator.
2. Measure the insulation resistance of the generator and excitation circuit.

TOTAL M/H 1.0
ELAPSED TIME: 1.0

SAFETY PRECAUTIONS

1. Observe standard safety precautions.
2. Wire air starting valve shut and tag "Do Not Open." On electric start system, disconnect starting motor at battery terminals and tag "Out Of Service."

TOOLS, PARTS, MATERIALS, TEST EQUIPMENT

1. 500-volt Megger
2. AN-PSM-4 Multimeter
3. 8" Screwdriver
4. 8" Adjustable wrench
5. Wire, 24 gauge
6. Safety tags
7. 6" Slip-joint pliers
8. Voltage tester
9. Lint-free rags
10. Vacuum cleaner

PROCEDURE

NOTE 1: Measure the insulation resistance weekly, when securing the generator, and before starting a generator that has been idle for one week or more.

Preliminary

a. Wire air starting valve shut and tag "Do Not Open." On electric start system, disconnect starting motor at battery terminals and tag "Out Of Service."
b. Open generator circuit breaker and tag "Out Of Service." Test with voltage tester to ensure generator side of circuit breaker is de-energized.
c. If installed, open disconnect links and tag "Out Of Service."

1. Clean the Generator.
   a. Remove inspection covers.
   b. Vacuum all interior surfaces and components that can be reached without disassembly of the generator; wipe with dry rags.

(Cont'd on Page 2)

Page 1 of 2 | EA | ZZZG | GG3 | 85 | 8624

LOCATION | W

Procedure (Cont'd)

2. Measure the Insulation Resistance of the Generator and Excitation Circuit.

NOTE 2: Measure the stator insulation resistance at the generator side of the generator circuit breaker.

a. Measure the insulation resistance of the stator, using 500-volt megger.
b. Lift the brushes. Measure the insulation resistance of the field from a slip ring to ground, using 500-volt megger.

CAUTION: Do not megger the excitation circuit.

c. Measure the insulation resistance of the excitation circuit from a brush holder to ground, using the multimeter.

NOTE 3: If insulation resistance is less than 0.5 megohm, take corrective action.

CAUTION: Do not snap springs in place; this may crack or chip the brushes.

d. Lower the brushes and reinstall cover.
e. Remove wire and tags. Reconnect starting motor, as applicable.
f. Set up for prescribed operation.

Page 2 of 2 | EA | ZZZG | GG3 | 85 | 8624 | W

98.176

Figure 6-28.—Maintenance Requirement Card.

175 11461

propulsion generators, motors, and exciters in electric drive ships. Record results of the tests on the appropriate megger cards.

QUARTERLY:

1. Inspect pulleys, belts, belt guards, mounting-frame bolts, end-shield bolts, and mechanical fastenings for mechanical soundness and tightness.
2. Check clearance between bearings and shaft on machines with sleeve bearings.
3. Check air gaps, if accessible for measurement, on machines with sleeve bearings. Record measurements taken on appropriate electrical history card.
4. Check end play of motor and generator shafts.
5. Rotate motors through one complete turn and inspect the commutator.
6. Replace wornout brushes.
7. Inspect and tighten brush "pigtails."
8. Check brush alignment parallel to commutator segments.
9. Check distance of brush holders from the commutator.
10. Check bush pressure.
11. Make sure that brush holders are clean and that the brushes move freely in the holders.
12. Blow out and clean motors thoroughly to remove dirt from the commutator, ventilation ducts, and insulation.
13. Measure and record the insulation resistance and temperature of motors.
14. Operate motors at normal load and temperature.

SEMIANNUALLY:

1. Drain, flush out, and renew oil in sleeve bearings.
2. Add grease to ball bearings if required. Record the date and the fact that the machine was lubricated.
3. Inspect all gaskets, particularly lubricant seals. Replace worn gaskets and seals.
4. Inspect armature banding and slot wedges.
5. Inspect the connections of armature coils to commutator risers.
6. Inspect and tighten all electrical connections.
7. Inspect commutator clamping ring.
8. Clean out slots in the commutator and undercut mica if necessary.
9. Inspect the ends of cage rotors for evidence of loose or broken bars or localized overheating.
10. Inspect fans for loose or broken blades.
11. Thoroughly clean all generators.

ANNUALLY:

Inspect all windings and insulation. Clean and repair insulation as necessary.

EVERY TWO YEARS:

Remove bearing caps or other covers as may be provided and observe the condition of ball bearings and lubricant. If no repairs are indicated, flush out the old grease, and replace with fresh, clean grease.

11462

CHAPTER 7

BATTERIES

This chapter further describes the principles of battery operation contained in Basic Electricity, NavPers 10086-A, and also includes battery maintenance procedures. The EM must give the same careful attention to the operation of storage batteries as he gives to the operation of any other power unit.

DRY BATTERIES

A dry (primary) cell is a unit source of d-c electrical energy derived from chemical action. Dry cells are of the (1) Leclanche, (2) mercury, and (3) low-temperature types. One or more dry cells constitute a dry battery. A dry battery is not completely reversible, and therefore cannot be recharged economically after it has been discharged. Dry batteries are easily transported from place to place and are used as a source of electrical energy to supply circuits that require a low and intermittent current.

LECLANCHE CELL

The Leclanche cell has a nominal open-circuit voltage of 1.5 volts. The positive electrode is a mixture of manganese dioxide and powdered carbon in contact with a carbon rod or plate. The negative electrode may be a piece of zinc sheet, compressed zinc powder or a zinc can. The electrolyte is a paste consisting of ammonium chloride (sal ammoniac), a small amount of zinc chloride and mercuric chloride, water, and starch. The electrical energy is obtained from reactions between the zinc, sal ammoniac, and manganese dioxide, as described under "Battery Chemistry, Dry (primary) Cells" in Basic Electricity, NavPers 10086-A.

MERCURY CELL

The mercury cell has a nominal open-circuit voltage of 1.3 volts. The positive electrode is a mixture of mercuric oxide and carbon. The negative electrode is a zinc plate, compressed zinc powder, or zinc foil. The electrolyte is an aqueous solution of potassium hydroxide. The battery is enclosed in a steel container. The electrical energy is obtained from the reduction of mercuric oxide to metallic mercury and the oxidation of zinc to zinc oxide.

ALKALINE-MANGANESE DIOXIDE CELLS

Cold weather operation at -40° F will reduce the capacity of these cells to approximately 9% of the 70° F capacity, whereas the Leclanche cells are inoperative at -10° F. At 70° F this battery provides about double the capacity requirement for the standard Leclanche cell of similar volume. These cells have a greater cost than Leclanche cells.

HIGH-TEMPERATURE CELL

Magnesium type dry cells have been developed which are capable of withstanding temperatures over 115° F for longer periods of storage time without excessive capacity loss. This type battery is for special purpose use primarily in hot humid climates.

The mercury cell, alkaline manganese dioxide and magnesium cells have superior characteristics for special applications, but are not used as extensively as the Leclanche cell because of the greater cost.

CLASSIFICATION

Dry cells are usually cylindrical or flat, and are manufactured in a wide variety of sizes

77 11463

and weights. The classification and requirements for dry batteries used in the Navy are contained in the Military Specification MIL-B-180, dry batteries. This specification lists the type/number, voltage, initial and delayed performance under a specified load, size, and weight of military dry batteries.

Label

In addition to specification sheets for individual battery types, all dry batteries are labeled to provide installation and replacement data (fig. 7-1). This data includes the type designation and code number.

The TYPE DESIGNATION comprises (1) the battery component, (2) battery type number, and (3) installation indicator.

The battery component denoted by the symbol, BA, identifies a dry battery.

The battery type number, 236, following the component symbol, identifies the basic design of the battery and the kind of cell with which it is assembled. Battery type numbers 1 to 999 inclusive indicate Leclanche cells; 1,000 to 1,999 inclusive indicate mercury cells; and 2,000 to 2,999 inclusive indicate obsolete type low-temperature cells.

The installation indicator denoted by the symbol, /U, indicates general utility service. This symbol follows battery type numbers of 200 and above.

The CODE NUMBER, 036, identifies the date of manufacture. The first two digits, 03, indicate the third month (March) and the last digit, 6, indicates the year (1966).

The remainder of the label data includes the manufacturer's name and address.

Terminal Markings

The terminals of a dry battery are indicated with the proper polarity markings, which appear on the top or side of the battery as close as possible to the applicable terminal. The location of the polarity markings depends on the type of terminal, which can include wire leads, Fahnestock clips, binding posts, sockets, and flat caps.

CHARACTERISTICS

Dry cells are rated in volts and hours for various conditions of operation. In other words, the capacity of a dry cell is determined by the length of time required before the terminal voltage drops to a specified end value when the cell is discharged continuously through a fixed resistance. The time is in hours and the load is in ohms. The operating conditions that determine the discharge characteristics of a dry battery are the (1) initial capacity, (2) delayed capacity, and (3) high-temperature storage capacity.

MIL BATTERY BA-236/U
1958-PHILA.-51-7
036
J & J MFG. CO.
PLAINFIELD, N. J.

77.86

Figure 7-1.—Dry battery label.

Initial Capacity

The initial capacity is the time required at normal temperature for the battery voltage to fall below the specified test end voltage, or to show evidence of electrolyte leakage, or swelling of the case when discharging through a specified load.

Delayed Capacity

The delayed capacity is the time required at normal temperature for the battery voltage to fall below the specified test-end voltage, or to show evidence of electrolyte leakage, or swelling of the case after the battery has been stored for a period of time.

High-Temperature Storage Capacity

The high-temperature storage capacity is the time required, after three months humid storage at 113° F., for the battery voltage to fall below the specified test-end voltage, or to show evidence of electrolyte leakage or swelling of the case.

INSTALLATION

Applicable installation practices and safety precautions must be followed when installing

CODIL 78 41464

dry batteries. Fresh batteries of the proper type, size, and shape should be installed initially or as a replacement for a specific installation. They must be connected in accordance with the instructions furnished with the equipment, and all electrical connections should be clean, tight, and well insulated.

If equipment is idle for two weeks or more, remove the batteries, and if such batteries are fairly fresh, return them to storage, with a record showing how long they have been used. Remove and scrap batteries that have had long and hard use.

STORAGE

Dry batteries are perishable and will deteriorate when not in use. To minimize deterioration, they should be stored at temperatures (equal to or less than 35° F in refrigerated spaces that are not dehumidified (dry)). If a refrigerated space is not available, they should be stored in the coolest space possible where they will not be subjected to excessive dampness or large variations in temperature.

Specifications require dry batteries to be wrapped in small unit packages, the unit packages are then sealed in polyethylene plastic bags. This method of wrapping helps to protect the batteries from outside temperature and humidity. The polyethylene bags should not be removed until the batteries are needed for actual use.

Any battery taken from refrigerated storage should be allowed to warm up to between 65° F and 80° F before use in order to obtain maximum battery capacity.

Batteries should not be shipped or stored in the equipment with which they are to be used because they may become discharged by internal chemical reaction or by leakage currents across normally open contacts. These conditions generate water within the cells, and electrolyte may leak out and corrode the equipment. To ensure reliable operation, install fresh batteries in the equipment as near as possible to the time that it will be operated. To avoid damage from electrolyte leakage, remove dead batteries from the equipment.

Shelf Life

The shelf life of dry batteries is the length of storage time beyond which a group of batteries will contain so many dead cells that the entire group is considered unusable. Shelf life depends not only on the kind and size of a cell but also on the application. Batteries containing the smaller cells do not retain their capacity as well as those containing the larger cells. As to use, the shelf life is less for a battery that requires a high initial capacity and a low internal voltage drop on discharge than for a battery that requires less initial capacity retention and a high internal voltage drop on discharge. Shelf-life tables are issued by the various supply offices. These tables are based on general use requirements and indicate a longer shelf life than is tolerable for more critical applications.

The assignment of a certain shelf life to a specific type of battery signifies that a substantial percentage, but not all, of the batteries in the group will be usable if the end of the shelf life is not reached. Test the usability of an individual battery by trying it out in the equipment for which it is to be used or by connecting it to an equivalent load and measuring the closed-circuit voltage. If this voltage is above that required for satisfactory equipment operation, the battery is suitable for use. Always survey batteries when they have reached the end of their shelf life.

Issue

No known nondestructive tests will show the amount of capacity remaining in a battery after it has been partially discharged or stored for a considerable length of time. It is usually good practice to issue the oldest batteries first if they are to be used in the close proximity of the warehouse where replacement stock is readily available. However, batteries issued for use aboard ship where premature failure would cause serious inconvenience, should be less than 6 months old.

SAFETY PRECAUTIONS

Certain types of batteries generate hydrogen, which is very explosive. When working with these batteries, interrupt the current at a remote point before disconnecting them from the equipment.

When a battery is disconnected from the operating equipment, the wire lead terminals of the battery should be insulated to prevent the possibility of a short circuit, which might generate sufficient heat to cause a fire. Also,

00014465

the discharge caused by a short circuit usually produces excessive water in the cells, thereby causing them to burst and spill corrosive electrolyte onto the equipment.

Multicell dry batteries should not be used after the closed-circuit voltage has dropped below 0.9 volt per cell. If the battery is further discharged, current will be forced through some cells that may be completely discharged. This action will generate hydrogen and oxygen due to the electrolysis of the water, with the consequent danger of a hydrogen explosion.

The 300-volt B section of the Navy type 19026 pack battery is capable of imparting a very serious, if not fatal, shock to anyone coming in contact with its terminals.

Mercury-cell batteries may explode if improperly handled. Never discharge a mercury-cell battery after the battery fails to operate the equipment or the voltage falls below 0.9 volts per cell. Never impose a "dead short circuit" on a mercury cell or allow a battery to become overheated. A 400° F temperature is sufficient to cause a mercury cell to explode. Exhausted mercury-cell batteries should be discarded as soon as possible. If not swollen, the steel jackets should have holes punched into them to release any gas which might be formed. If the cells are swollen, either bury them or discard them at sea.

STORAGE BATTERIES

A wet (secondary) cell is a unit consisting of positive and negative plates, separators, cell covers, and electrolyte, properly assembled in a single jar or in one compartment of a monobloc case (molded in one piece). A tray consists of one or more cells assembled in a common container or monobloc case. One cell, one tray of cells, or a number of trays of cells connected in series, parallel, or series-parallel constitutes a storage battery. A storage battery is reversible because the active materials consumed during discharge can be restored by passing a charging current through the battery. The storage cells in general use are the nickel-cadmium and lead-acid types.

NICKEL-CADMIUM CELL

The nickel-cadmium (Ni-Cad) cell is an alkaline storage cell. It is used in aircraft, guided missiles, space satellites, electronic consoles, and for the initial pulse to excite generator fields in some installations. The construction and general arrangement of the cell are similar to that of the lead-acid cell. The negative plate assembly is a cadmium-oxide compound; the positive plate assembly is a nickel-oxide compound; and the electrolyte is a 30 percent solution of potassium hydroxide. Separators between the positive and negative groups prevent internal short circuits. The cell components are assembled in a single plastic jar. The battery case is of fabricated steel. A 6-volt battery contains 5 series-connected cells. When fully charged, the cell voltage ranges from 1.39 to 1.45 volts.

The sealed Ni-Cad battery requires only recharging, no water is added, no hydrometer readings are taken. These batteries are supposed to last a lifetime.

At first glance, the Ni-Cad battery appears to be the answer to all portable power requirements. These batteries are available in sizes ranging from a small button of 20-milliampere-hour capacity to a large 160-ampere-hour cell. Cells are connected in series to obtain higher voltages. The batteries may be vented or hermetically sealed to make them leakproof and capable of operating in almost any position. With proper design, gassing due to overcharging is practically nil.

The Ni-Cad battery may be used over a wide temperature range. It may be stored at -40° F to 140° F and discharged at a maximum temperature of 160° F or a minimum of -60° F if necessary.

The Ni-Cad battery has been tested under extreme weather conditions in Alaska and Arizona for use in automotive equipment. The electrolyte in the Ni-Cad batteries will withstand the same temperature extremes in either the charged or discharged condition. The avoidance of freezing of the battery in the discharged condition has resulted in its increased use in airplanes. With all the decided advantages of the Ni-Cad battery, its use is still limited to a few applications onboard naval ships. The disadvantages of the battery must be weighed against the desirable characteristics. For example, a size D (flashlight size) Ni-Cad battery costs 40 to 60 times as much as the ordinary dry cell. A savings from using small rechargeable batteries on shipboard could not be demonstrated. For engine-starting batteries, the Ni-Cad battery costs 5 to 10 times as much as the lead acid battery. Depth of discharge,

aaa11466

Figure 17-30. —Azimuth-marker oscillator circuit.

Marker Mixer

The method of combining all the various markers is accomplished by the tubes V1, V2, and V3. (See fig. 17-31.) V1 has the range markers applied to its left grid and the right grid is returned to the variable-delay trigger tube. The TD marker is fed directly to the right grid of V1 and will appear on the indicator as a variable marker when the control unit controls are properly set up for TD marker operation.

V2 has its left grid returned to a cable marked L. A. B. This cable would normally be coupled to the low-altitude bombing equipment and place the tracking pip from the bombing equipment on the radar indicators. The right grid of V2 is returned to a cable marked IFF-IR. This cable, normally attached to the IFF equipment, applies the interrogator response return, which is the IFF display on the radar indicators. In operating the IFF and radar system together, the radar transmitter pulse is used to trigger the IFF equipment, which can then be used to interrogate another IFF equipment. The coded return from the other IFF is then applied to the radar indicators. The distance from the transmitter pulse to the first return will be the distance from the radar to the target and the bearing will be determined by the position of the return on the indicators.

V3 has its grid returned to R300 (fig. 17-30), the azimuth-marker amplitude control. The output of the azimuth-marker circuit, a 1-megacycle sine wave, is applied to this grid and will appear on the indicators as a sudden reduction in bias for several sweeps, giving the appearance of a bright line at the marker control heading.

The markers are all combined in the common cathode circuits of the marker mixers and at the junction point of the two cathode resistors R5 and R6. The signal across R6 is coupled through C2 to the grid of V4, one of the marker-output tubes. Also, the signal or signal are coupled through C3 to the grid of V5, the other marker-output tube. Each of these marker-output tubes controls the markers applied to an indicator.

The combining point in any radar system is its indicating device. V6 combines the video from the receiver and the markers from the marker-output tubes. V6 and V7 would be located in the indicator.

The video from the receiver is positive-going video pulses, which have been acted on by the video mixing circuit and the receiver. These positive-going video signals appear negative in the plate of the video-marker mixer V6. Into the right-hand grid of the video-marker mixers are fed the range markers, the amplitude of these markers being controlled by the marker brilliance control R11. Note that the cathode of V6 is unbypassed, so that the

1144

temperature, and recharging have a drastic effect on the cycle life of these batteries. Claims of a lifetime of use from these batteries do not tell the whole story. If operated at the optimum temperature of 75° F the Ni-Cad battery may be charged and discharged 5,000 to 7,000 times, if the discharge does not exceed 25 percent. However, if the same battery is discharged 75 percent the cycle life is reduced to a few hundred cycles. If the battery is operated at below 0° F, the life cycle is lowered to less than 100, even with shallow discharges. At temperatures above 100° F the electrolyte reacts with the separator material, causing shorting and loss of capacity.

Unbalanced cells in a Ni-Cad battery are a source of possible trouble during charging. A phenomenon known as "thermal runaway" may occur when these batteries are placed on constant voltage charge. As the end of the charging cycle is reached, the overcharging current produces heat. Increased temperature reduces the electrolyte resistance which, in turn, permits a greater current flow, and more heat develops. Constant current charging avoids thermal runaway but may lead to hydrogen evolution. Unless compensated for in the battery design, this can lead to bulging cases or even an explosion of sealed batteries.

The only possible way to determine the state of charge of a Ni-Cad battery is to keep a record of the ampere-hours that have been taken out of the battery since it was fully charged. A voltage test only indicates if the battery has a charge or is discharged. The specific gravity would be meaningless in determining the state of charge; however, since many batteries are sealed, no hydrometer reading can be taken on those batteries anyway. The only answer is to keep the batteries fully charged, ready for use at all times. This alone can be a maintenance problem. Ni-Cad cells should not be connected in parallel due to minor differences in the internal resistance of the cells. This could result in excessive currents in some cells during charging and perhaps polarity reversals in others. If more ampere hours are desired a battery of greater capacity should be used. As technology improves, the undesirable characteristics of the Ni-Cad battery will be minimized and you will find them in wider use onboard ship. As previously stated many Ni-Cad batteries are sealed, however the more expensive, vented type are also in use and may be found in certain installations.

Charging Ni-Cad Cells

The effect of the charging current is to change the active material of the negative plate (cadmium-oxide) to metallic cadmium (Cdo to Cd). The active material of the positive plate (nickel-oxide) is changed to a higher state of oxidation NiO to Ni_2O_3. As long as the charging current continues, this action occurs until both plates are completely converted. Toward the end of the charging process and during overcharge, the cell will gas due to the electrolysis of the water in the electrolyte. This action liberates 4 atoms of hydrogen gas ($2H_2$) at the negative plate for every 2 atoms of oxygen gas (O_2) liberated at the positive plate. The amount of gas liberated depends on the charging rate.

The electrolyte does not enter into any chemical reaction with the positive or negative plates. It acts simply as a conductor of current between the plates, and its specific gravity does vary appreciably with the amount of charge. The effect of the reactions during charge is a transfer of oxygen from the negative to the positive plates. In this respect the nickel-cadmium storage battery is similar to the lead-acid storage battery. Unlike the lead-acid storage battery the specific gravity of the electrolyte remains constant, except at the end of a charge or on overcharge, when it increases because of the electrolysis of the water. The proper specific gravity on vented cells can be obtained by adding distilled water.

Nickel-cadmium batteries can be charged by the (1) constant voltage, (2) constant current, and (3) stepped constant-current methods. The most efficient performance is obtained when the charging rate is such that 140 percent of the rated ampere-hour capacity of the cell is delivered to the cell within a 3-hour interval.

Discharging Ni-Cad Cells

When the cell is connected to an external circuit containing a resistance, the chemical action which occurs is the reverse of that of the charging process. The negative plate gradually regains oxygen (Cd to CdO), and the positive plate gradually loses oxygen (Ni_2O_3 to NiO); that is, the action during discharge effects a transfer of oxygen from the positive to the negative plates. There is no gassing on discharge due to the interchange of oxygen. The discharge process is the conversion of the chemical energy of the plates into electrical

1467

energy. The rate at which this conversion occurs is determined by the external resistance, or load, to which the battery is connected. The internal resistance of the cell is extremely low because of the cell construction.

LEAD-ACID CELL

The lead-acid cell is the storage battery most extensively used in the Navy. As explained in Basic Electricity, NavPers 10086-A, the positive-plate assembly consists of lead peroxide; the negative-plate assembly is pure sponge lead; and the electrolyte is a mixture of sulphuric acid and distilled water.

Charging

The effect of the charging current is to change the lead sulphate formed on both the negative and positive plates by the reaction of the electrolyte with the active material, back to the original active form of lead peroxide ($PbSO_4$ to PbO_2) on the positive plate and sponge lead ($PbSO_4$ to Pb) on the negative plate. At the same time the sulphate is restored to the electrolyte, and the specific gravity of the electrolyte increases. When all of the sulphate is restored to the electrolyte, the specific gravity is maximum and the cell is fully charged. Toward the end of the charging process, hydrogen (H_2) is liberated at the negative plate, and oxygen gas (O_2) is liberated at the positive plate. This action is due to the electrolysis of the water in the electrolyte. Hydrogen is an odorless highly explosive gas. Care must be taken to avoid sparks of any kind. Adequate ventilation is also important to reduce the hazard of explosion.

Discharging

When the cell is connected to an external circuit containing a suitable load resistance, the action of the electrolyte on the active material of the negative and positive plates causes a current to flow. Thus, the chemical energy stored in the plates is transformed into electrical energy as the cell discharges. The reaction of the electrolyte with the active material forms lead sulphate on both the negative and positive plates. As the discharge continues, the acid content of the electrolyte becomes less as it is used in forming lead sulphate, and the specific gravity of the electrolyte decreases. When so much of the active material in the cell has been converted into lead sulphate that it can no longer produce sufficient current to be of practical value, the cell is discharged.

CLASSIFICATION

The classification and requirements for storage batteries used in the Navy (except for aircraft and automotive vehicles) are contained in the Miltary Specification for Portable Lead-Acid Storage Batteries, MIL-B-15072B (ships). This specification includes other pertinent information concerning these batteries.

Storage batteries are classified as Class ER, electrolyte-retaining and Class FE, free-electrolyte batteries. Class ER batteries have separators and plates that absorb and retain within the cell at least 80 percent of the electrolyte, and operate with not more than 20 percent of the electrolyte in a free condition. Class FE batteries operate with at least 50 percent of the electrolyte in a free condition. The automotive type batteries are contained in the Military Specification for Lead Acid Storage Batteries, MIL-B-11188C. The Navy type batteries under MIL-B-15072B (ships) are of heavier construction and provide longer life.

Nameplate

Supplementary to the specification sheets supplied for the individual battery types, all storage batteries are provided with nameplates that contain installation and replacement data (fig. 7-2). The TYPE DESIGNATION contained on the nameplate is in the same form as that previously described for dry batteries. It comprises the battery component, battery type number, and installation indicator.

The battery component denoted by the symbol, BB, identifies a lead-acid storage battery.

The battery type number, 256, following the symbol, identifies the basic design of the battery. Batteries designed for low-temperature operation are identified by increasing the established battery type number by 2,000. For example, a low-temperature battery is identified if the established battery type number, 256, is increased to 2256.

The installation indicator denoted by the symbol, /U, indicates general utility service. Battery type numbers of 200 and above have this /U symbol appended.

Prior to the Military Specification (MIL-B-15072B), Navy standard batteries were identified

11468

77.87

Figure 7-2.—Storage battery nameplate.

according to voltage, use, and rating. This former type designation, CLASS 6V-SBM-100AH, also appears on the nameplate (fig. 7-2).

The voltage of the fully charged battery denoted by the symbol, 6V, identifies a 6-volt battery.

The use of the battery denoted by the symbol, SBM, identifies a monobloc storage battery. Other uses denoted by symbols, SBP and SBMD, identify portable and monobloc diesel-starting storage batteries, respectively.

The rating of the battery denoted by the symbol, 100AH, identifies a battery that can supply 100 ampere-hours when discharged at the 10-hour rate (10 amperes x 10 hours = 100 ampere-hours).

The remainder of the data contained on the nameplate requires no explanation.

Terminal Markings

The positive and negative terminals of storage batteries are legibly indicated by POS or P and NEG or N, respectively. These polarity markings are raised or depressed characters placed on, or as close as possible to, the applicable terminal. For further identification of the battery polarity, portions of the positive and negative terminals that are not contact surfaces can be painted red and black, respectively.

CHARACTERISTICS

Capacity

The capacity of a storage battery is the constant current that the battery can supply continuously at a definite rate of discharge before the voltage drops below a specified limiting (final) voltage. This capacity varies with the rate of discharge; that is, the lower the rate of discharge the greater the capacity, and vice versa.

Discharge Rate

Navy storage batteries are rated at the 10-hour discharge rate, which is the constant current in amperes that the battery (starting with an initial electrolyte temperature of 80° F) can supply continuously for 10 hours before the voltage drops to the low-voltage limit. Other hourly discharge rates are defined similarly.

Final Voltage

The final voltage, or low-voltage limit, is that (set by the manufacturer) beyond which very little useful energy can be obtained from the battery. Generally, the low-voltage limits for batteries at different rates of discharge vary slightly with the size and make of the battery. At the conclusion of a discharge at the 10-hour rate, the closed-circuit voltage will be approximately 1.75 volts per cell, and the specific gravity will be approximately 1.060. At the completion of a charge, the closed-circuit voltage at the finishing rate will be approximately 2.4 to 2.6 volts per cell, and the specific gravity will be from 1.210 to 1.220 at 80° F.

INSTALLATION

Lead-acid storage batteries are shipped (1) filled and charged and (2) dry. When shipped to naval ships they are usually in the filled and charged condition. When shipped to replenish stock at naval shipyards or other shore establishments, or on board repair ships or tenders, they are usually in the dry condition.

Charged And Wet

When batteries are shipped (filled and charged), the cells are completely assembled, contain electrolyte, and are sealed ready for use. When batteries are received in this

11469

condition, the height of the electrolyte should be examined, and specific gravity and temperature readings should be taken of all cells to ascertain the state of charge.

If there is no evidence of spilling or leakage, and the height of the electrolyte is below the bottom of the filling tube or the level mark on polystyrene cells, sufficient distilled water should be added to bring the level even with the bottom of the filling tube or the level mark. Unless otherwise specified, the electrolyte level should be three-eighths of an inch above the separators.

If the electrolyte has been spilled during shipment, it should be replaced with electrolyte of 1.215 specific gravity corrected to 80° F.

Charged And Dry

The instructions for charged and dry batteries are similar to those for the uncharged and dry with a few exceptions. When the electrolyte is placed in the cells they will have a 70 - 80% charge and are available for immediate use in case of emergency. It is preferable to first give it a thorough equalizing charge after filling. The charged and dry batteries must be stored in a cool dry location until ready for use, and under these conditions the plates will retain most of their charge for perhaps as long as two years. Once it has been properly prepared, its capacity, life and characteristics are the same as a new "wet" battery.

If water or electrolyte is added, the battery should be charged at the finishing rate until specific gravity readings, corrected for temperature, are constant for a period of 5 hours. If the battery is not to be placed in service immediately, an equalizing charge should be given at 1-month intervals, or sooner if the specific gravity has dropped to 1.180, and again just before placing it in service.

Uncharged And Dry

When batteries are shipped dry, the cells are completely assembled and sealed, but contain no electrolyte, and the plates are in the uncharged condition. When batteries are received in this condition and are not to be placed in service, the vent plugs must be kept tightly in place and the batteries stored in a clean dry space until they are required.

If the battery is to be placed in service, follow the instructions contained on the accompanying tag. These instructions specify the specific gravity of the electrolyte to be used in filling the cells, the time to allow for the electrolyte to soak into the plates before charging, the temperature limit, and the method for conducting the initial charge.

Only authorized personnel at repair activities are permitted to fill a cell or battery with electrolyte. Electrolyte of a specified specific gravity is added until its level is even with the bottom of the filling tube or the level mark on polystyrene jars. The battery will become heated when filled with electrolyte and should be allowed to stand for at least 12 hours to cool before starting the initial charge. The battery should not stand for more than 24 hours (after filling) before starting the charge. During the standing period the level of the electrolyte will drop because it soaks into the plates and separators. The level should be restored to the prescribed height by adding electrolyte of the same specific gravity as used initially, before starting the charge.

Placement in Service

When batteries are to be placed in service, the trays are arranged so that the positive terminal of one tray can be connected to the negative terminal of the next tray throughout the battery. If the battery terminals, or posts, are not properly marked, the polarity can be determined by means of a d-c voltmeter across the terminals. If a voltmeter is not readily available, immerse the terminal leads in salt water, holding them about one-half inch apart. Bubbles will collect on the negative lead. Do not allow the leads to touch each other when conducting this test.

The contact surfaces of battery terminals are usually covered with a thin film of acid, which should be neutralized and removed to prevent corrosion before making the connections. For this purpose, diluted ammonia or a solution of bicarbonate of soda can be used, exercising care not to allow the solution to enter the cells. After the contact surfaces have been neutralized, they should be brightened with a wire brush or fine sandpaper. The contact surfaces are then bolted together and coated with petrolatum or cup grease.

All connections should be checked to make certain that the polarity is correct and that all exposed metal in the connectors is protected with petrolatum or cup grease. The top and sides of the battery should be cleaned with a

11470

cloth dampened in a solution of dilute ammonia or bicarbonate of soda, after which the battery should be thoroughly washed with pure water.

Battery Numbering

Batteries must be assigned a number to provide a systematic method of identification and to facilitate the maintenance of battery records. This identification is accomplished by assigning a number to each tray. For example, if a ship has a total of 100 trays of portable storage batteries for all purposes, each tray is numbered consecutively from S62-3(1), S62-3(2) and so on, to S62-3(100). In addition, the cells of a tray are numbered consecutively, beginning at the positive end.

The battery number should be stenciled in a conspicuous place on the side of the container for ready identification. When a new tray replaces an old one, give it the number of the old tray, and begin a new log.

Pilot Cells

Pilot cells (one from each tray) must be selected at random from which cell readings are taken during routine inspections and tests. The cell readings provide an approximate indication of the battery condition without the necessity of taking readings of all the individual cells.

Records

Where applicable, ship maintenance card will be used in lieu of form NavShips 151, Storage Battery Tray Record. This form will be inspected and approved monthly by the electrical officer or in the case of radio batteries by the radio officer and note of such inspection and approval will be made on the form at that time. The record shall accompany the battery tray whenever transferred. It may be destroyed when the service of the battery is terminated. NavShips 151 will be kept when ship Maintenance Cards are not used.

STORAGE

Storage batteries, like dry batteries, deteriorate when not in use. Batteries in a wet condition should not be stored for considerable periods of time. When batteries are to be stored temporarily, they should be placed in a clean, dry space at an average temperature of 75° F and never subjected to temperatures below 50° F or above 100° F. Batteries that have a capacity of 80 percent or more when taken out of service should be maintained in a fully charged condition and issued at the first opportunity.

Wet Storage

When placing batteries in wet storage, give them an equalizing charge, and coat (with petrolatum) all exposed terminals to prevent corrosion. The batteries are then placed on racks, located in the battery locker, to allow free circulation of air around the top and sides.

Batteries in wet storage must be inspected at frequent intervals, and the electrolyte level maintained above the tops of the separators. Give these batteries an equalizing charge each month, or more often if the specific gravity falls below 1.180, and maintain a battery tray record during the period that the battery is in wet storage.

Acid

Carboys containing sulphuric acid must be stored in spaces where freezing cannot occur. The freezing temperatures of sulphuric-acid electrolyte depend on the specific gravity of the solution and vary over a wide temperature range, as indicated by the specific gravity versus temperature curve shown in figure 7-3. For example, the freezing temperature of sulphuric acid having a specific gravity between 1.614 and 1.667 is indeterminate (drops rapidly) below -40° F. On the other hand, if the specific gravity of concentrated acid is reduced from 1.835 to 1.800, the freezing temperature changes from -29° F to +42° F.

Because sulphuric acid is highly hygroscopic (readily absorbs and retains moisture), the carboys must be kept absolutely airtight. If a small quantity of water is allowed to enter a carboy containing sulphuric acid, it can reduce the specific gravity sufficiently to freeze (in cold weather) the solution, causing the carboy to break, with the consequent danger of acid burns to personnel. At any temperature, the addition of a small quantity of water to concentrated sulphuric acid can cause an explosion with the sudden evolution of heat.

MAINTENANCE

Lead-acid storage batteries will deteriorate rapidly if they are not maintained properly and

STAT 1471

77.88

Figure 7-3.—Specific gravity versus temperature curve.

kept fully charged. The actual life of these batteries is indeterminate, but when properly cared for the Navy types should give a useful life of four or more years, depending on the type and use.

Care

The service for which a battery is used primarily determines the nature of the care and maintenance that will ensure maximum reliability and life.

ENGINE-STARTING BATTERIES.—Batteries that are used to start propulsion engines, motor-boat engines, and ship's service engine-generator sets are subjected to moderately heavy use and may require frequent charging in addition to the charging provided by the engine generator. If the specific gravity has dropped 30 points below the prescribed operating value of specific gravity, give the battery an equalizing charge, taking care that it is not overcharged by the engine generator. To prevent overcharging, set the charging rate of the engine generator to maintain the specific gravity of the electrolyte about 20 points below the prescribed operating specific gravity.

AUXILIARY LIGHTING AND POWER BATTERIES.—Batteries on stand-by service for auxiliary lighting and power are seldom discharged by actual use. A normal battery on open circuit will discharge 50 percent or more in a period of 3 or 4 months. This is a normal condition and is usually called local action or self-discharge. The lead sulphate formed during self-discharge is more difficult to reduce by charging than the lead sulphate formed during a regular discharge. Therefore, stand-by batteries should be given an equalizing charge when the specific gravity drops to 1.180, and at 30-day intervals, irrespective of the specific gravity (if the batteries are on open circuit and not delivering power). If the monthly equalizing charges fail to maintain the prescribed specific gravity, the batteries should be cycled to restore them to a normal condition.

TELEPHONE, F.C., AND I.C. BATTERIES.—Batteries on stand-by service for dial telephones, fire control, and interior communications are usually floated on a low-voltage supply line from motor-generators through reverse-current circuit breakers. Batteries for automatic telephones are intermittently charged automatically from motor-generators that supply the telephone system.

GUNFIRING BATTERIES.—Batteries used for gunfiring and sight-lighting purposes are idle a large part of the time. These batteries should be given an equalizing charge once a month, or when the specific gravity drops to 1.180. These batteries should also be cycled to restore them to a normal condition if the monthly equalizing charge fails to maintain the specific gravity of the electrolyte above 1.180.

COUNTER E.M.F. CELLS.—Counter E.M.F. cells are normally the responsibility of the IC Electrician as they are used in automatic telephone circuits. However, the Electrician's Mates on certain ships may be required to stand watches in the IC room and should therefore be aware of the appearance and purpose of the counter E.M.F. cells.

These cells have the same outward appearance of the usual storage battery tray, but they are distinguished by the letters "C.E.M.F." on the nameplates. The cells consist of electrodes immersed in an electrolyte but have no storage capacity. The cells are used to produce an opposing voltage in order to reduce the voltage

172 121672

of one circuit to the desired lower voltage on a dependent circuit. Counter E.M.F. cells perform substantially the same functions as a rheostat but differ from the latter by interposing a fairly constant voltage. In operation, the counter E.M.F. cells, decompose the water in the electrolyte practically in proportion to the ampere-hours which pass through them. This results in the evolution of gas, and, therefore the cells need to be filled with distilled water from time to time.

ROUTINE INSPECTIONS

Routine inspections of batteries should follow along with the Planned Maintenance System as well as with Naval Ship Systems Command instructions.

Routine inspections of batteries are necessary to ascertain good operating conditions. The following schedule of inspections is considered to be the minimum requirements consistent with good engineering practice for batteries used under average operating conditions. However, if experience indicates that these inspections are not sufficient to ensure that the batteries are capable of performing their functions when needed, the frequency of inspections should be increased as necessary. For example, in cold weather operations, it may become necessary to make daily inspections of boat batteries.

Daily Inspections

The ventilation system in battery rooms and battery lockers should be inspected daily to ascertain that all parts of the system are in properly operating condition. Also, battery hydrometers should be cleaned daily to prevent the accumulation of sticky substances that collect on the float inside the barrel, and result in inaccurate readings. The hydrometer parts should be cleaned with an ammonia solution, flushed with clear water, dried, and allowed to air before they are reassembled.

When assembling or disassembling a hydrometer, a heavy piece of cloth should be wrapped around the glass barrel to prevent injury in case of glass breakage. During reassembly, the rubber-bulb should be moistened slightly with water where the rubber contacts the glass barrel. This will reduce the amount of pressure or torque required to replace the bulb.

Weekly Inspections

The specific gravity and temperature readings of pilot cells for all batteries should be taken and recorded each week. The batteries should be watered if the height of the electrolyte in the pilot cells is at the low mark. Pure distilled water can be added to a battery at any time to replace that which has spilled or evaporated. However, it is preferable to add water just prior to placing the battery on charge in order to mix it with the electrolyte. Otherwise, in cold weather, if the water is allowed to remain on top of the electrolyte, it may freeze and crack the monobloc cases or jars. The charging rate of engine battery-charging generators and the voltage at which batteries are being floated should be checked each week to prevent overcharging.

Monthly Inspections

All batteries, except those that are charged by an associated engine generator or those that are being floated, should be given an equalizing charge each month. A complete set of voltage, temperature, and specific gravity readings should be taken on these batteries at the completion of the equalizing charge. Batteries should be cleaned and inspected for broken or cracked cases. The terminals should be coated with petrolatum, if necessary, to prevent acid from coming in contact with the connections. Sulphate is formed when acid attacks these parts, making it difficult to disconnect leads from the terminals. Also, the sulphate increases the resistance of the terminal connections, with a consequent reduction of the voltage on discharge. Battery connections should be examined and all faulty conditions corrected.

Quarterly Inspections

All batteries that are charged from an associated engine generator or are being floated should be given an equalizing charge each quarter. A complete set of voltage, temperature, and specific gravity readings should be taken on these batteries at the completion of the equalizing charge.

Functional Testing

1. A functional test is a method to determine if a battery is sufficiently operational to

11473

provide energy to operate specific equipment for a period of time. Test discharges are the most reliable means of determining a storage battery's condition. Functional testing may be done in lieu of a test discharge only when authorized by a Ships Maintenance Card.

2. Functional testing of Navy type portable storage batteries for various shipboard applications vary with usage, size of battery and load. The test requirements are as follows:

a. Engine starting batteries
The batteries will be capable of starting an engine at least once a week.

b. Portable lantern batteries
The batteries will be capable of providing sufficient light for a period of one minute without any diminuation of intensity and be tested at least once a week.

c. Gyrocompass batteries
The gyrocompass batteries will be functionally tested for a 20 minute period on battery power alone monthly.

d. Telephone batteries
Telephone batteries will be functionally tested during a peak load period for 4 hours on battery power alone monthly.

e. Functional testing of other portable storage battery service not covered above may be obtained upon request from the Naval Ships Engineering Center. This information will be required for new types of applications.

3. If the functional test fails, the batteries shall be given an equalizing charge and retested. If the retest fails the failed batteries shall be replaced.

CHARGING

It is not possible (in one chapter) to cover all of the different types of battery chargers or charging switchboards found on various ships or stations. However the following types are representative of those in use.

Battery Charging And Discharging Switchboards

The battery charging and discharging switchboard of a large aircraft carrier is a good illustration of the type of control required for charging a variety of portable storage batteries. The main features of the switchboard may best be analyzed by examining the schematic diagram in figure 7-4.

The various charging circuits of the switchboard are fed through a manually operated circuit breaker from either a 450-volt a-c supply through a rectifier (120 v d-c) or from a 120-volt d-c supply from one of the d-c switchboards. The circuit breaker is equipped with reverse current trip to prevent feedback from the batteries should there be a power failure. Indicating lights are provided to show when power is available.

Trickle charging circuits are provided for charging batteries at a slow rate. The representative system shown in figure 7-4 can charge several batteries at the same time through the charging resistor circuits.

Double-pole double-throw transfer switches are used for charging and discharging batteries through a fixed resistance and a variable rheostat. Setting the variable rheostat controls the magnitude charging or the discharging current.

The charging current or discharging current of any battery circuit can be read from an ammeter when the ammeter selector switch is closed to the proper circuit. There are two ammeters for this purpose. One is connected to battery circuits having a maximum charging rate of 40 amperes and the other to circuits having a maximum charging rate of 20 amperes. A third ammeter (not shown) is connected directly in the source circuit for reading the total current supplied to the board.

A voltmeter (not shown) with two selector switches is installed with connections to the various charging circuits. The two selector switches are interconnected to provide the number of positions required.

The front view of a typical battery charging-discharging switchboard for an aircraft carrier is shown in figure 7-5.

The latest type battery charging switchboards being furnished to the fleet are constructed with self-contained rectifier circuits and operate directly from 440-volt, 3-phase, 60-cycle alternating current ship's service system. This design eliminates the need for a separate rectifier, and in some cases has permitted deletion of a ship's service direct current system. Outputs of the charging circuits are controlled by magnetic amplifiers or, in smaller ratings, by rheostats. Figure 7-6 is a typical circuit of a switchboard using integral rectifiers. The switchboards with integral rectifiers are very similar to the older type in appearance and operation. They require no

11676

27.68

Figure 7-4.—Elementary wiring diagram of battery charging and discharging switchboard.

reverse current relays, since the rectifier elements prevent the discharge of connected batteries into the switchboard. Because it is impossible to discharge a battery with a rectifier type switchboard charger, battery dischargers (usually portable) are furnished where required. Figure 7-7 is a typical battery discharger.

cathode would tend to follow the video-frequency rise on the grids of both sides of the tube. This degeneration improves the fidelity, or frequency response, as cathode degeneration will do, although the cathode resistor, R13, is quite small by comparison with the plate-load impedance. Also to improve the frequency response in the plate is the high frequency response peaking circuit of L1.

The negative-going video and markers are coupled through C6 to the grid of the video amplifier, V7. The signals in the plate would be positive-going. In the cathode circuit is the degeneration control, R19, the master brilliance control. In order to simplify the explanation of this control, it should be pointed out that adjusting the resistance of R19 will in no way change the bias on the tube, but by controlling the amount of degeneration present in the cathode, the amplitude of the plate signals can be controlled. The simple deduction would be to say that the increased resistance of R19 would decrease conduction through the amplifier, or reduce the output, and that a decrease in the resistance of R19 would increase the amplitude of the signals in the plate of this amplifier. In the plate circuit are the high frequency peaking components, L2. The positive output from V7 is fed to the final video amplifier.

AZIMUTH STABILIZATION

Most azimuth stabilization systems are similar, and an understanding of one system will provide information that will be helpful in the comprehension of other systems.

An azimuth stabilization system stabilizes the indicator screen presentation, causing the display to remain rotationally fixed despite changes in the heading of the aircraft. By this means, a definite compass relationship is established for the indicator screen, and radar target echoes appear in proper position with respect to the top center of the screen, which represents magnetic north. The stability of the indicator presentation also facilitates search during rough weather or moderate maneuvering of the aircraft.

Figure 7-7.—Battery discharge resistor panel wiring diagram.

A battery charging-discharging switchboard of the type installed in certain destroyers is illustrated in figure 7-8. This switchboard is located in the battery compartment and consists of a single dead-front type of panel comprising an upper (hinged) section and a lower (removable) section. The upper panel section contains the necessary meters, indicating lights, and power circuit breaker. The lower panel section contains the required rheostats, ammeter switches, and circuit switches.

This switchboard is provided with two local circuits and two remote circuits for charging and discharging lead-acid storage batteries in trays of three cells each. Each tray comprises a 6-volt battery. The two local circuits (1 and 2) are designed for charging and discharging 50 ampere-hour and 100 ampere-hour batteries. The two remote circuits (3 and 4) are designed for charging and discharging 175 ampere-hour, motor boat and diesel-engine batteries, respectively. The 4 charging and discharging circuits are capable of handling from 1 to 12 batteries of the prescribed capacities in series. Two transfer switches are provided so that the remote circuits can be used also as local circuits.

The 120-volt, d-c power for charging batteries is normally supplied to the switchboard over the battery-charging feeder from the forward d-c generator and distribution switchboard. A type ACB power circuit breaker provides overload and reverse current protection, as indicated by the schematic diagram (fig. 7-9).

11478

77.89

Figure 7-8.—Battery charging and discharging switchboard.

When the normal power supply is not available, a limited supply (20 amperes, maximum) can be obtained from the I.C. switchboard over a limited capacity feeder. This limited power is supplied through a DPDT selector switch, the midpoint of which is connected to the charging circuit through the power circuit breaker on the switchboard. This selector switch is mounted on the base of the power circuit breaker, and its position can be changed only by opening the upper (hinged) section of the panel. A white indicator light (w) indicates when power is available from the I.C. switchboard. The majority of battery charging-discharging switchboards are not designed to supply the limited power from the I.C. switchboards, and therefore are not equipped with the feeder selector switch and white indicator light.

The power circuit breaker, located in the center of the upper section, is a manually operated, 2-pole, 250-volt, 100-ampere, type ACB breaker. It is equipped with two over-current coils and an undervoltage coil. The over-current coils can be calibrated from 100 to 200 percent of the breaker rating, and the undervoltage coil functions to trip the breaker on low voltage to prevent discharging the batteries. An amber (A) and a blue (B) light located directly above the circuit breaker indicate the OPEN and CLOSED positions, respectively, of the breaker.

A double-scale voltmeter having scales of 0 to 15 volts and 0 to 150 volts is located at the top on the left-hand side of the upper section. This voltmeter is provided with a 6-position switch for (1) cutting out the voltmeter, (2) reading the voltage of only one of the four switchboard circuits, or (3) reading the bus voltage. A scale-changing switch is also provided for changing to the low-voltage scale when taking voltage readings on only one or two batteries. The scale-changing switch must remain in the high-scale position, except when actually taking low-voltage readings, because of possible overloading, with consequent damage to the voltmeter.

A single-scale voltmeter having a scale of 0 to 3 volts is located adjacent to the double-scale voltmeter. This voltmeter is connected to a jack receptacle centrally located near the top of the lower section. A 15-foot cord having a plug at one end and battery test clips at the other end is provided for taking voltage readings of single cells in a battery. The test leads of this cord and plug must not be connected to more than one cell at a time because of possible overloading of the voltmeter.

Two ammeters having scales of 0 to 20 amperes and 0 to 40 amperes are located at the top on the right-hand side of the upper section. These ammeters are provided for taking current readings of circuits 1 and 2 and 3 and 4, respectively.

A SPDT, spring-loaded ammeter switch, located directly below the associated rheostat handle on the lower section, is provided for

114

77.90

Figure 7-9.—Schematic wiring diagram of battery charging and discharging switchboard.

1148911

each of the four switchboard circuits. The ammeter switch is used to take readings of the charging and discharging current for the associated circuit when the switch is held in the ON position. Only one ammeter switch of each set of circuits (1 and 2 or 3 and 4) should be closed at any one time because of the possibility of overloading and damaging the ammeter.

A rheostat, located on the lower section, is provided for each of the four switchboard circuits. These rheostats are used when charging or discharging batteries to cut IN or to cut OUT sufficient resistance in order to obtain the necessary current flow for the number of batteries connected in the associated circuits at the time.

A DPDT, charging and discharging switch for each of the four switchboard circuits and a DPDT local and remote transfer switch for each of the two remote circuits (3 and 4) are located at the bottom of the lower section. The local battery charging and discharging circuits are connected to a terminal block in the rear of the battery switchboard. The remote battery charging and discharging circuits are connected to the common terminal (stud) of the two local and remote DPDT switches.

The charging and discharging rates for the battery switchboard are contained in the manufacturer's instruction book. These rates should not be exceeded because overloading can damage either or both the switchboard circuits and batteries.

When batteries are charged, the voltage of the charging line must exceed the total voltage of the batteries connected in series to be charged. When more than one tray is to be charged in series, the negative terminal of one tray is connected to the positive terminal of the next tray, irrespective of the number of trays connected. After the trays are connected in series addition, the remaining positive terminal on the first tray and the remaining negative terminal on the last tray are connected to the corresponding positive and negative terminals of the charging circuit. If the batteries are of different sizes, the charging rate in amperes must not exceed the maximum charging rate of the lowest rated battery in the series. The maximum charging rates are obtained from the battery nameplates. For example, a series-connected line containing two 6-volt batteries and one 12-volt battery with maximum charging rates of 5, 7, and 10 amperes respectively, must be charged at a 5-ampere rate.

Gassing

When a battery nears full charge, the voltage rises to about 2.35 volts per cell and the battery begins to gas freely. When gassing begins near the end of the charge, the charging current must be decreased to the finishing rate to avoid heavy gassing.

Excessive gassing is an indication that the battery is being charged too rapidly, and the rate must be reduced. Otherwise, the gas bubbles will tend to loosen the active material from the plates and eventually cause disintegration of the positive grids. This loosened, active material is precipitated to the bottom of the cell, resulting in loss of battery capacity. An internal short circuit will result if this accumulation of active material reaches the bottom of the plates. Also, excessive gassing increases the danger of a hydrogen explosion.

Initial Charge

An initial charge is a long, low-rate, forming charge that is given to a new battery (uncharged and dry) to place it in service.

To conduct an initial charge, fill the battery with electrolyte of the proper specific gravity, and replace the vent plugs, making certain that the vent holes are clear. The battery should be allowed to cool before beginning the charge.

The battery is connected to the charging and discharging switchboard, and all the resistance is cut in by means of the rheostat.

The battery switch is closed to the charging position, and the rheostat is adjusted until three-fourths of the finishing rate (obtained from the nameplate) is indicated by the ammeter. The rheostat is further adjusted when necessary to maintain the proper charging rate.

Hourly readings of the voltage, temperature, and specific gravity are taken. If the temperature of the battery reaches 125° F, the charging rate is either reduced or discontinued until the battery cools. The charge is continued after the battery cools until the voltage and specific gravity have remained constant for a period of at least 5 hours.

The number of ampere-hours for the initial charge should never be less than five times the rated capacity at the 10-hour rate, as specified on the nameplate. If this rate is maintained, the battery will require approximately 84 hours of charging.

11481
S8411

After the initial charge is completed, the specific gravity should be adjusted (corrected to 80° F) to that specified on the nameplate, as explained in Basic Electricity, NavPers 10086-A. The capacity of all Navy standard portable batteries, except Class 2V-SBP-20AH, is based on a fully charged electrolyte between the limits of 1.210 and 1.220 specific gravity at 80° F. Class 2V-SBP-20AH batteries are always operated with electrolyte specific gravity between the limits of 1.270 and 1.285. If the electrolyte has been mixed carefully, very little adjustment should be necessary.

The date of the initial charge must be stamped or scribed legibly in the space provided on the nameplate. The date of the initial charge is important because it indicates the beginning of the useful life of the battery.

Normal Charge

A normal charge is a routine charge that is given in accordance with the nameplate data during the ordinary cycle of operation to restore a battery to a fully charged condition.

To conduct a normal charge, ascertain the proper charging rates for starting and finishing the charge from the nameplate data. Add distilled water to each cell to bring the electrolyte to the proper level, and replace the vent plugs. Connect the battery to the switchboard (the positive terminal to the positive side and the negative terminal to the negative side) and cut in all the resistance. The battery switch should be closed to the charging position and the rheostat adjusted until the proper charging rate is indicated by the ammeter. As the battery voltage rises, the rheostat is adjusted to maintain this charging rate.

Hourly readings are taken of the voltage, temperature, and specific gravity of the pilot cells during the charge. The battery temperature should not exceed 125° F. The charging rate is decreased to the finishing rate when the battery begins to gas freely or when the voltage reaches 2.35 volts per cell. The finishing rate should not exceed that specified for the particular battery.

The normal charge is completed when the specific gravity, corrected for temperature, has reached a value within five points (0.005) of that obtained on the preceding equalizing charge.

Equalizing Charge

An equalizing charge is an extended normal charge that is given a battery at the finishing rate. It is given periodically to ensure that all the sulphate is driven from the plates and that all the cells are restored to a uniform maximum specific gravity. To conduct an equalizing charge, continue the normal charge at the finishing rate and take 30-minute readings of the temperature and specific gravity.

The equalizing charge is continued until the hydrometer readings, corrected for temperature, show no increase in corrected specific gravity for any cell over a period of 4 hours.

All Navy standard batteries are given an equalizing charge at 30-day intervals, except for engine-starting batteries and batteries normally on floating charge, which are given an equalizing charge at 90-day intervals.

Floating Charge

A floating charge is given a battery that is standing idle or used on stand-by service to maintain it in a fully charged condition.

To conduct a floating charge, connect the battery across a power line that has a voltage maintained between the limits of from 2.13 to 2.17 volts per cell in the battery. The charging rate is determined by the battery voltage, not by a definite rate of current. The voltage is adjusted periodically to maintain an average of 2.15 volts per cell. Special equipment is necessary to give a battery a floating charge. If this equipment is not included with the battery-charging panel, a battery is maintained by giving it monthly equalizing charges.

Emergency Charge

An emergency charge is given to recharge a battery in the minimum amount of time. The charging rate is much higher than is normally used for charging. This charge can be accomplished by using the (1) constant-potential and (2) modified constant-potential (multiple-step) methods.

The constant-potential method employs a starting rate sufficiently high to bring the voltage up to about 2.35 volts per cell. If gassing starts, lower the voltage until gassing occurs only slightly, and use this voltage as the charging voltage. Maintain this voltage, with a steady decreasing current, until the finishing

18MI
GSMI 11482

rate is reached. The finishing rate is held constant until the charge is completed. The charge can be stopped at any time, but it should be completed if possible.

The modified constant-potential method is started at about 2.25 to 2.30 volts per cell. The current rate obtained at this starting voltage is maintained until the voltage increases to 2.35 volts per cell. At this time the charging rate is dropped to a lower rate. This lower rate is continued until the voltage again increases to 2.35 volts per cell, and the charging rate is again dropped to a lower rate. The charge is continued in successive steps until the finishing rate is reached. At this time no further reduction in the charging rate is made.

The constant-potential and modified constant-potential methods of conducting an emergency charge cannot be used for charging cells of different sizes.

TESTS

State of Charge

The specific gravity of the electrolyte gradually decreases on discharge and gradually increases on charge. This decrease and increase is nearly in direct proportion to the number of ampere-hours taken out of, or put back into, the battery, and is thus a check on the state of charge at any time. As explained in Basic Electricity, NavPers 10086-A, the state of charge, or the number of ampere-hours, expended by a battery can be determined from the (1) specific gravity when fully charged; (2) specific gravity after the battery has been discharged; and (3) reduction in specific gravity per ampere-hour. The voltage alone is not a reliable indication of the state of charge, except when approaching the low-voltage limit on discharge, and hence should not be used for this purpose.

Test Discharge

A test discharge is the best method of determining the capacity of a battery. All Navy standard portable batteries must be given a test discharge at least once every 6 months. Also, a test discharge must be given when the cell voltage and specific gravity fall below specified limits at the completion of a periodic equalizing charge. The cell voltage readings are compared with the values indicated by the cell voltage versus electrolyte temperature curve (fig. 7-10).

77.91

Figure 7-10.—Cell voltage versus electrolyte temperature curve.

The battery should be given a test discharge if any cell has a voltage that is less than that shown on the curve for the corresponding electrolyte temperature, or if the specific gravity of one or more cells cannot be brought up to within 0.010 of the full charge, irrespective of whether the voltage after the equalizing charge is satisfactory (equal to or greater than the value indicated on the curve). To ensure that reliable data is obtained, a test discharge must be preceded by an equalizing charge.

To conduct a test discharge, connect the battery to the charging and discharging switchboard, and cut in all the resistance by means of the rheostat. The battery switch is closed to the discharging position, and the rheostat is adjusted for the proper 10-hour discharge rate. For example, the correct discharge rate for a 200 ampere-hour battery is 200/10, or 20 amperes. The 10-hour discharge rate is continued until (1) the total battery voltage drops to a value that is equal to 1.75 times the number of cells in series, or (2) the voltage of any individual cell drops to 1.65 volts, whichever occurs first.

If a battery has 100-percent capacity, the discharge will continue for a period of 10 hours before reaching the low-voltage limit, provided the temperature of the electrolyte at the beginning of the discharge is exactly 80° F. Otherwise, the time duration of the discharge for 100-percent capacity must be corrected for the actual electrolyte temperature existing at the start of the test.

11483

The corrections, in the time to be applied to the 10-hour rate for 100-percent capacity for various temperatures of electrolyte, can be obtained from the electrolyte temperature versus time curve shown in figure 7-11. The corrections, in the time of discharge indicated by the curve, apply only to the 10-hour rate.

As explained in Basic Electricity, NavPers 10086-A, the ampere-hour capacity of a storage battery is calculated from the equation,

$$C = \frac{H_a}{H_t} \times 100$$

where C is the percentage of ampere-hour capacity available, H_a the total hours of discharge, and H_t the total hours for 100-percent capacity. If the ampere-hour capacity is 80 percent or more, the battery should remain in service; whereas, if it is less than 80 percent, the battery may be discarded.

77.92

Figure 7-11.—Electrolyte temperature versus time curve.

TROUBLES

The most common trouble encountered in the operation of storage batteries is that of low cells. The specific gravity of low cells is usually below that of the other cells, both on charge and discharge; hence, the expression, LOW, refers to specific gravity. This condition is caused by poor connections, sulphation, loss of active material, local action, short circuits, loss of electrolyte, hardened negative plates, disintegration of positive grids, broken positive pencils (iron-clad), and impure electrolyte. Low cells can be detected by progressive loss of capacity, low voltage on discharge, low specific gravity, abnormally high or low voltage on charge, and abnormally high temperature.

When trouble is experienced with any cell, it should be examined immediately for low electrolyte, poor connections, and voltage readings should be taken at the cell terminals while the battery is being charged or discharged. If the voltage readings are appreciably higher or lower than that of normal cells, the trouble is probably within the cell and must be investigated further.

SULPHATION

Sulphation is one of the most common causes for the failure of cells to maintain their normal charge. Consequently, low cells are often erroneously attributed to sulphation, with the result that the actual defective condition is not remedied but aggravated by the sulphation treatment.

Sulphated cells are indicated by a falling off of the specific gravity, low voltage on discharge, and loss of capacity.

A sulphated condition will result in batteries that are given undercharges or partial charges, or if they are not given periodic equalizing charges. In normal battery operation it is difficult to determine when sulphation begins. The only way that sulphation can be detected in its early stages and corrected or prevented is by giving the required equalizing charges and comparing the specific gravity and voltage readings of individual cells.

A battery that is allowed to stand in a partially charged condition will become sulphated when the sulphate deposited on the plates hardens and closes the pores in the material. Batteries should be charged as soon as practicable after discharge, and they should never be allowed to stand in a completely discharged condition for more than 24 hours.

If the level of the electrolyte is permitted to fall below the tops of the plates, the exposed surfaces will harden and become sulphated. Also, a cell in which sulphation exists becomes aggravated with the addition of acid.

In general, sulphation is more likely to occur and will be more difficult to reduce in fully charged cells that have high values of specific gravity. The possibility of sulphation is increased in cells that have a specific gravity of 0.015 or 15 points above the average. High temperatures accelerate sulphation, particularly in idle, partially charged batteries.

Sulphation of a battery, except in extreme cases, may be reduced by a long charge, finished at a low rate. The charge should be started at the highest available rate that can be utilized without excessive gassing, and continued at progressively reduced rates to keep within the allowable temperature limits before the charging current is reduced to the finishing rate. This procedure breaks down the sulphate that has not been reduced by previous normal charges. The finishing rate is approximately

$$\underline{FR} = \frac{1.1 \times AH_{10}}{20} \qquad 0.055 \times \underline{AH}_{10}$$

where $\underline{FR}$ is the finishing rate in amperes, and $\underline{AH}_{10}$ is the ampere-hour capacity at the 10-hour rate. The charge is continued at this rate until the specific gravity and voltage are constant for a period of 5 hours.

To measure the results of this treatment, compare the specific gravity and voltage readings with similar readings of healthy cells in the battery. These readings are also considered in conjunction with the capacity of the battery, as indicated by a test discharge. If the comparison is satisfactory, the battery has been restored to a normal condition, and no further treatment is necessary. Otherwise, the sulphation treatment should be repeated.

Loss of Active Material

A normal loss of active material occurs in all batteries due to erosion caused by gassing at the end of a charge. An excessive loss of active material can be caused by too much gassing, overcharging, and expansion due to high temperatures.

Excessive shedding results in a reduction of capacity. It is a sign of wear and is often evident in batteries that have given long service. One of the first indications of shedding is a slightly muddy appearance of the electrolyte caused by the lead peroxide in suspension. There is no remedy for active material that has already left the plate. Additional shedding can be prevented by reducing the rate of charge, particularly at the end of a charge. Some batteries are provided with a mat of spun glass placed against the positive plate to retard the loss of active material after it has become soft and muddy.

Local Action

Local action, or internal discharge, is indicated by an excessive drop in the specific gravity of the electrolyte when the cell is on open circuit. This condition is also indicated by excessive gassing when the cell is on discharge. In general, the higher the specific gravity, the greater will be the tendency for local action, and the more rapidly the specific gravity will fall when the battery is standing idle.

Internal discharge is caused by impurities and non-homogeneity of the material in the plates or by impurities in the electrolyte. Internal discharge is sometimes caused by sediment in the bottom of the jar or by broken separators, which also cause considerable gassing.

Iron is the most common impurity. If impurities are suspected, the electrolyte should be dumped, and the plates should be rinsed with distilled water. The cells should be refilled with new electrolyte of the same specific gravity as that discarded and given an equalizing charge.

Short Circuits

Short circuits are indicated by abnormal temperature, low specific gravity, low voltage, and reduced gassing on charge. Short circuits can be caused by (1) faulty separators, (2) lead particles or other metal forming a circuit between the positive and negative plates, (3) buckling of the plates, (4) excessive accumulation of sediment in the bottom of the jar, (5) mossing that usually occurs between the tops of the negative plates and the positive straps, and (6) a cracked partition between cells in a monobloc case.

11485

A cell that contains a short circuit will gradually discharge and will become unduly heated on charge. The element should be removed and examined to determine the cause of the short circuit. If mossing or sediment caused the faulty condition, the cell should be removed and the element replaced in the container. The element should be replaced also if the separators are damaged or if the plates are badly worn.

Loss Of Electrolyte

Loss of electrolyte is indicated by an excessive drop in the level of electrolyte compared with that of normal cells, and this indicates a crack in the jar or case.

Hardened Negatives

Hardened negatives are the result of the formation of a hard, nonporous material on the negative plates. This condition could be detected if the battery was disassembled by scratching the active material. A healthy plate is easily scratched and shows a bright metallic luster. A hardened plate contains a hard, insoluble coating, which is difficult to remove. Normally this condition is only viewed at repair activities where batteries are repaired.

Reversal of Cell Voltage

A low cell, in series with other cells, may reverse its polarity when discharged considerably below its low-voltage limit. If this action occurs before the adjacent cells are near their low-voltage limit, it should be assumed that the condition is caused by faults within the cell.

A reversed cell can be detected by a voltage reading of the cell and it (reversed cell) will cause a rapid fall in the battery voltage. This fall in battery voltage may be as much as 3 or 4 volts because the cell voltage may change from 1.7 volts in the proper direction to as much as 2.0 volts in the reverse direction in a short time. Except in an emergency, as soon as a reversed cell is detected, the battery must be taken out of service until the cell is repaired.

REPAIRS

Major repairs to batteries must be performed only by authorized personnel at naval shipyards or other shore establishments.

For information on battery repairs, read chapter 9622 of the NavShips Technical Manual.

Electrolyte is mixed and added to batteries only by authorized personnel at repair activities or on tenders and repair ships.

Mixing Electrolyte

The preparation of electrolyte requires special facilities and precautions. To prepare electrolyte, lead or rubber vessels and stirring rods are necessary. Every effort must be made to keep all impurities from the electrolyte while mixing, since impurities shorten battery life. Only pure distilled water and sulphuric acid (Federal Specification O-S-811) shall be used. NavShips Technical Manual (chapter 9622) includes a table showing the amounts of water and acid to be used to make electrolyte of a desired specific gravity. Personnel handling or mixing electrolyte must wear rubber aprons, rubber boots, and rubber gloves, so that the acid may not come in contact with the skin or clothing. In particular, the eyes must be protected by goggles. In mixing electrolyte the acid must be poured into the water. NEVER pour the water into acid. The acid must be poured slowly into the water to prevent excessive heating. The solution should be stirred continually while the acid is being poured, this prevents the heavier acid from flowing to the bottom without mixing. When concentrated acid is diluted, the solution becomes very hot even when properly mixed. If the solution is not continually stirred while mixing or is mixed wrong (pouring the water into acid) an explosion may occur resulting in serious injury to personnel and damage to equipment.

In the event of an accident or carelessness in handling electrolyte or acid, prompt treatment for acid burns is essential. Should a man get concentrated acid or electrolyte on his skin, wash the affected area freely with large quantities of fresh water, apply vaseline, petroleum jelly, boric acid, zinc ointment, or, if none of these are available, clean lubricating oil, and send him to sick bay. A small amount of water may not only be ineffective in preventing a serious burn, but may even do more harm than good.

If acid or electrolyte gets into the eye, first wash with plenty of fresh water. Repeatedly squeeze out a saturated gauze pad or wad of cotton held above the eye, the water being directed into the pocket formed by pulling the

In the following discussion of azimuth stabilization, an instrument called a fluxgate compass is used. The fluxgate compass employs most of the principles relative to so-called "earth field inductors," and later model compasses operate on those same principles.

Stabilization of the indicator screen pattern is accomplished by signal voltages controlled by the master indicator of the fluxgate compass (also called fluxvalve compass) in the aircraft. These signals are used to control the angle of the sweep trace on the screen in accordance with the instantaneous azimuth position of the scanner.

In order to explain the theory of operation of azimuth stabilization, it is necessary to analyze briefly one of the compass systems used. This is necessary since in an equipment that contains azimuth stabilization the compass that controls the stabilization is an intricate part of the system. The GYRO FLUXGATE COMPASS SYSTEM of the aircraft is a remote-indicating earth-indicator compass, which consists of a gyrostabilized fluxgate, transmitter, an amplifier, a master indicator, and one or more synchro remote-indicator repeaters. (NOTE: The term "gyro fluxgate" is a registered trade name of the Bendix Corporation.) The fluxgate element is stabilized in the horizontal plane by an electrically driven horizon gyro. The gyro head contains a rolling-ball type of erecting system, which maintains the gyro axis in the vertical plane by setting up a restoring force when the axis becomes displaced.

The transmitter portion contains the sensitive element of the system, the fluxgate unit, which consists of three equal legs forming a triangle; this unit is established and maintained in the horizontal plane by the action of the gyro. Each leg consists of two strips of a magnetic alloy used as a core upon which are wound a primary and a secondary coil. The primary coils are connected in series and are excited by an oscillator circuit in the amplifier. The secondary coils are delta connected, with leads tapped off at the points where the three coils join. These leads, and the single lead which supplies the excitation current, are brought out through hairsprings on the gimbal rings. The primary coil of each leg is wound in such a manner that when the leg is at right angles to the magnetic field of the earth the exciting alternating current produces opposing fluxes in each strip which neutralize each other and induce no voltage in the secondary. This exciting current saturates the core on the peak of each half cycle.

When the leg is parallel to the earth's magnetic field, the earth's flux tends to oppose the flux in one alloy strip and to aid the flux in the second strip. The partial cancellation of the flux in the first strip prevents its reaching saturation at the same time as the second strip, and its flux continues to change after the second strip has reached saturation. The flux difference thus set up induces a voltage in the secondary. When the current through the primary decreases to a point where the flux starts to drop below the point of saturation, a voltage in the opposite direction is induced in the secondary. This occurs because the flux in the first strip (in which partial cancellation exists) drops below the saturation point before the flux in the second strip, thus producing a flux change in the opposite direction. Since saturation occurs twice each cycle, and since secondary voltages are induced at the start and again at the finish of each period of saturation, the frequency of the induced voltage is double that of the primary voltage.

Three signal voltages, which generally are of three different magnitudes, are obtained from the fluxgate secondary coils, and are applied to the stator coils of a coupling synchro contained in the master indicator.

The voltage induced in the rotor winding of this synchro is fed to the fluxgate amplifier, which develops sufficient power to operate a 2-phase induction motor which is also in the master indicator. The fluxgate amplifier includes an extremely stable oscillator that is used to furnish excitation power for the fluxgate and another oscillator which provides voltage for the continuously excited winding of the 2-phase induction motor in the master indicator. The excitation voltage applied to the induction motor is necessarily at a frequency of twice that of the fluxgate excitation voltage in order to equal the frequency of the fluxgate output.

The 2-phase induction motor in the master-indicator phase unit has its stator wound in quadrature (two windings at right angles to each other). The control winding is energized by the amplified signal from the synchro rotor, and the exciting winding receives its power from the oscillator in the amplifier. When both windings of the induction motor are energized by voltages having a phase difference of 90°, the motor rotates and drives the synchro rotor

1146

lower eyelid outward. Do not use a syringe nozzle or any other pressure method for this purpose because of the danger of mechanical injury to the eye. The eye should be washed again with a solution made by mixing two tablespoonfuls of sodium bicarbonate (baking soda) in a pint of clean fresh water. After washing the eye, apply clean mineral oil or petrolatum and send the man to sick bay. In case an ample supply of fresh water is not available, electrolyte or sulphuric acid may be neutralized by applying quickly to the affected place a solution of sodium bicarbonate.

Increasing the Specific Gravity

If the specific gravity of any cell is dropped below the 1.210-1.220 limit, the affected cells are given a 4-hour equalizing charge. At the end of this charge, determine accurately the specific gravity and correct it for the electrolyte temperature existing at the time. For each point that the actual specific gravity of the cell is below 1.215, the amount of electrolyte to be withdrawn must be approximately equal to 1 percent of the total volume of electrolyte normally contained in the cell. For example, if the specific gravity of the low cell is 1.195, it will be (1.215-1.195) x 1000, or 20 points below normal. Thus, the amount of electrolyte to be withdrawn will be 20 x .01, or 20 percent, of the normal volume of electrolyte in the cell. The withdrawal must never lower the electrolyte level below the tops of the separators.

To ensure thorough mixing, the level of the electrolyte is restored to normal by adding electrolyte of 1.300 specific gravity while the cells are being charged and are gassing.

The affected cells are charged at the finishing rate for a 1-hour period. At the end of this period the specific gravity is accurately determined and corrected for the electrolyte temperature existing at the time.

The foregoing procedure is repeated as many times as necessary to increase the specific gravity of the affected cell within the limits of 1.210 to 1.220 at 80° F.

Decreasing the Specific Gravity

If the specific gravity of any cell is above the upper limit of 1.220, the affected cells must be given a 4-hour equalizing charge. At the conclusion of this period, the specific gravity is accurately determined and corrected for the electrolyte temperature existing at the time. For each two points that the specific gravity of the cell is above 1.215, the amount of electrolyte to be withdrawn must be approximately equal to 1 percent of the total volume of electrolyte normally contained in the cell. For example, if the specific gravity of the high cell is 1.230, it will be (1.230-1.215) x 1000, or 15 points, above normal. Thus, the amount of electrolyte to be withdrawn will be 15/2 x .01, or 7.5 percent, of the normal volume of electrolyte in the cell.

To ensure thorough mixing, the level of the electrolyte is restored to normal by adding pure distilled water while the cells are being charged and are gassing.

The affected cells are charged at the finishing rate for a 1-hour period. At the end of this period, the specific gravity is accurately determined and corrected for the electrolyte temperature existing at the time.

The foregoing procedure is repeated as many times as necessary to decrease the specific gravity of the affected cell below the 1.220 limit at 80° F.

SURVEY

It is the policy of Naval Ship Systems Command to discard batteries when it has been definitely ascertained that they cannot be made to give more than 80 percent of their rated capacity. Since a battery may be only temporarily low in capacity, care must be used in determining its true condition.

Scrapping Procedure

Batteries should not be scrapped unless it is definitely known they cannot be made to give further useful service. On the other hand, care must be taken to prevent loss of time and money in a effort to keep in service batteries that should be scrapped. When it is believed that a battery is unfit for further use, the following confirmatory procedures should be followed.

1. Give the battery an equalizing charge.
2. Discharge the battery at the 2-hour rate in accordance with NavShips Technical Manual, Chapter 9622. Compute the capacity obtained and compare it with the rated (nameplate) capacity.
3. If the battery delivers at least 80 percent of its rated capacity on test discharge and is

88-11487

in otherwise good condition; it should be recharged and returned to service.

4. Batteries which do not deliver at least 80 percent of their rated capacity on test discharge should be scrapped by the ship or activity using the battery upon approval of the electrical officer.

When portable storage batteries contained in hard-rubber monobloc cases are surveyed, the elements can be scrapped, but the cases should be cleaned, set aside, and credited in the Appropriation Purchases Account (APA). These cases are sent to repair ships and tenders for replacing damaged cases in reassembled or rebuilt batteries.

DATA REQUIRED

All requests for survey of portable storage batteries must contain the following information for each tray to be surveyed:

1. Name of manufacturer.
2. Navy type and manufacturer's type.
3. Purchase contract or order number.
4. Date of initial charge.
5. Service for which used.
6. Details of special treatments given to bring the battery (tray) to 80 percent of rated capacity or over.
7. Complete description of the condition of the battery at time of survey.
8. The Storage Battery Tray Record, NavShips 151, must accompany the survey request.

SAFETY PRECAUTIONS

Battery charging stations must be provided with adequate ventilation to remove the explosive mixture of hydrogen and air. As previously explained, when batteries are being charged, hydrogen gas is liberated; if the surrounding air contains from 4 to 8 percent hydrogen, a mixture is formed that will burn, if ignited. If the mixture contains more than 8 percent hydrogen, it will explode. Hence, ample ventilation is necessary to keep the hydrogen concentration below an established safe limit of 3 percent.

When a large number of batteries are concentrated in a single compartment, the ventilation problem becomes serious, and care must be exercised to ensure that the ventilating system is operating at all times. The system should be supplied with fresh air from the exterior of the ship, and the exhaust from the battery compartment should lead overboard. Battery explosions are dangerous and will result in serious injury to personnel, and in damage to equipment.

The ventilating system, in addition to preventing the formation of the explosive mixture, provides a means of keeping the temperature of the battery-charging station down to 95° F or lower; and thus facilitates the charging of batteries (the charging rate is limited to a value that will cause the electrolyte temperature not to exceed 125° F).

After a battery compartment that has been sealed is opened, it must be thoroughly ventilated before light switches are turned on, any other electrical connections made or broken, or work of any kind performed. Flames and sparks must be kept away from the vicinity because storage batteries give off a certain amount of gas at all times.

The ventilating system must be operating properly before starting a charge. The charge must be stopped if ventilation is interrupted; except in an emergency, the charge should not be resumed until the ventilation has been restored.

All batteries must be kept clean and free from the accumulation of acid and dirt; otherwise corrosion will occur and eventually lead to troublesome grounds. Grounds are formed by the collection of dirt and acid on the cell tops and sides of a battery. They will result in dissipation of battery energy and disarrangement of the circuit in which the battery is connected. Also, a ground in the vicinity of a battery can furnish a spark that will ignite an explosive mixture.

Acid that has collected on a battery can be removed with a cloth moistened in a solution of dilute ammonia or bicarbonate of soda. Also the top and sides of a battery should be cleaned after each watering.

A battery should always be charged at the prescribed rates; never at a higher finishing rate than that indicated on the nameplate. When charging more than one battery at the same time, the voltage of the charging line should be known to exceed the total voltage of all the batteries being charged in series. Also, the charging rate in amperes should be known not to exceed the maximum charging rate of the battery having the lowest ampere-hour capacity in the charging line. The charging rate should be lowered as soon as the battery begins to gas or the temperature reaches 125° F. Except

1844488

in an emergency, a battery should not be discharged below the low-voltage limit. As previously stated, a battery should never be allowed to stand in a completely discharged condition for more than 24 hours.

Only tools with insulated handles should be used while servicing a battery, and care should be exercised not to short circuit the terminals. No repairs to battery connections should be made when current is flowing in the circuit, and batteries should never be connected to, or disconnected from, the charging line without first turning off the charging current. When batteries are used with one terminal grounded, the grounded terminal should be disconnected (first) when replacing the battery. This action will avoid the possibility of grounding the hot terminal and shorting the battery when the ungrounded terminal is disconnected first.

Never allow salt water to enter a battery cell, as chlorine gas, which is extremely toxic, will be evolved.

Electrolyte having a specific gravity greater than 1.350 should never be added to a battery.

Keep on hand in the battery locker materials for treating acid burns.

Never permit smoking in the battery locker.

CHAPTER 8

PROTECTIVE DEVICES

The electrical distribution system and its associated generators can be easily damaged unless protected from various sources of trouble. Considerable protection can be acquired from automatic protective devices, provided they are not misused. However, it is extremely important for operating personnel to realize that no provision is made for automatic protection of a generator from damage by long continued operation at a current only moderately in excess of rated capacity. Sole reliance for this type of protection is placed upon the vigilance of the operator.

This chapter describes how and why protective devices are used. Because an important part of your duties is to maintain uninterrupted operation of equipment, you must understand the purpose of each device.

This knowledge will help you find the cause of interruption, clear the trouble, and restore operation with minimum loss of time.

Any trouble, whether due to overload or fault, must be cleared before a new protective device (for example, a fuse) is installed. Otherwise the new device will be ruined by the same defect that caused the original breakdown.

Protective devices may differ considerably in appearance and construction. Regardless of their appearance or construction, they are used only to protect equipment or personnel.

Most protective devices are designed to interrupt the power to a circuit when circuit conditions become dangerous.

The purpose, construction, and testing of protective devices will be described. When two devices are used on the same circuit, the purpose and operation of each device will be explained. By studying the equipment in this manner, you should be able to visualize power supply systems and the methods used to protect entire systems as well as individual branches.

FUSES

The simplest protective device is a fuse. All fuses are rated according to the amount of current that is safely carried by the fuse element. Usually, the current rating is in amperes, but some instrument fuses are rated in fractions of an ampere. When a fuse blows, it should be replaced with another of the same rated voltage and current capacity, including the same current-versus-time characteristic.

The most important fuse characteristic is its current-versus-time or "blowing" ability. Three time ranges for existence of overloads can be broadly defined as fast, medium, and delayed. FAST, may range from 5 microseconds through one-half second; MEDIUM, 1/2 to 5 seconds; DELAYED, 5 to 25 seconds.

Normally, when the circuit is overloaded, or a fault develops, the fuse element melts and opens the circuit that it is protecting. However, all fuse openings are not the result of current overload or circuit faults. Abnormal production of heat, aging of the fuse element, poor contact due to loose connections, oxides or corrosion forming within the fuse holder, and the heated condition of the surrounding atmosphere will alter the heating conditions and the time required for the element to melt.

DELAYED-ACTION FUSES

Some equipment, such as an electric motor, requires more current during starting than for normal running. Thus, a fast-time or medium-time fuse rating that will give running protection might blow during the initial period when high starting current is required. Delayed-action fuses are used to handle these situations.

One type of delayed action fuse has a heater element connected in parallel with the fuse element in order to get the delayed action. During normal operation the heat developed in the fuse

e8411490

link is not great enough to melt the link. The melting, or opening, of the fuse link depends on the transfer of heat to the link from the heater. Therefore, more time is needed to melt the link than would be required if the link were directly heated.

Because the heater and fuse element are in parallel, the opening of the fuse element will cause the total circuit current to flow through the heater. The high current will cause the heater to burn out and completely open the circuit.

Another type of delayed-action fuse has the fuse element and heater connected in series. Current above that of the rated value for a short time will have no effect on the fuse or heater. However, prolonged overloads cause the heater section to become hot enough to melt the junction between the elements; this action opens the circuit.

Delayed-action fuses are sometimes call Time-Lag fuses, and three trade names "Slo Blo," "Fusestat," and "Fusetron" are in common use.

PLUG FUSES

The plug fuse is constructed so that it can be screwed into a socket mounted on the control panel or distribution center. The fuse link is enclosed in an insulated housing of porcelain or glass. The construction is so arranged that the fuse link is visible through a window of mica or glass. Therefore, an open element may be located by visual examination. The plug fuse is used primarily to protect low-voltage, low-current circuits. The operating ratings range from 0.5 to 30 amperes up to 150 volts.

Except in certain older gyrocompass repeater panels, the plug fuse is seldom found aboard naval ships. It is used extensively in shore installations. When found to be defective, the fuse is discarded and a new fuse installed in its place.

CARTRIDGE FUSES

In operation, the cartridge fuse is exactly the same as the plug fuse. In construction, the fuse link is enclosed in a tube of insulating material with metal ferrules at each end (for contact with the fuse holder). The dimensions of cartridge fuses vary with the current and voltage ratings.

Table 8-1 lists some of the fuses in use on board naval ships. Note the different dimensions and ratings.

Because an arc is produced when excessive current causes the fuse link to open, the fuse tube is filled with materials, such as shredded asbestos or boric acid, which act as an arc quencher.

BLOWN-FUSE INDICATORS

It is not always possible to detect a blown fuse by a visual examination. Hence, fuses are often equipped with a device that will provide a visual indication so that a blown-fuse condition can be readily detected (fig. 8-1). These devices consist of the spring-loaded and the neon-lamp types of blown-fuse indicators.

In the spring-loaded type (fig. 8-1A) when the link opens, it releases a spring that is held under tension. This action exposes an indicator, which makes the visual location of the blown fuse possible.

The neon-lamp type (fig. 8-1B) is designed to be mounted on the fuse. When the link opens, a neon lamp glows to show a blown fuse.

When no indicator is used, it is necessary to test the fuse continuity with a megger, ohmmeter, or voltmeter. Various methods of testing will be described later in this chapter.

Most fuse panels and switchboards are of the enclosed panel type. The term "dead-front," means that all fuses and bus connections are enclosed in a metal cabinet when the cover is closed. The use of this type of construction reduces the possibility of equipment damage and danger to personnel. Modern switchboards are of the "dead-front" type.

However, the complete enclosure of the equipment makes it less accessible for test purposes. Therefore, most fuses used on "dead-front" switchboards have indicators that show when a fuse is blown. The fuse holder consists of a molded phenolic base, plug, and cap with a built-in indicator lamp (blown-fuse indicator). The lamp is usually a small neon bulb, which normally is shunted by the fuse element. When the fuse opens, the shunt is removed, causing an increase in the voltage across the neon lamp. The lamp then glows, indicating the open fuse.

TROUBLESHOOTING FUSED CIRCUITS

The complete electrical system of a ship may consist of a comparatively small number of

sebrr11491

Table 8-1.—Fuse Characteristics

Style	Available current ratings (amperes).	Maximum permissible voltage of circuit in which used.	Blowing characteristics on overload when mounted in open clips (all fuses must blow promptly on short circuit).
F03 (1-1/4" long by 1/4" dia)	0.01-30	125	Within 1 hour on 135% rated current. Time lag: Within 6 seconds on 300% rated current.
F09 (1-1/2" long by 13/32" dia)	.1-30	125	Within 1 minute on 150% rated current. Time lag: Within 6 seconds on 300% rated current.
F60 (1-1/2" long by 13/32" dia)	1-30	500	Within 1 minute on 150% rated current.
F15 (2" long by 9/10" dia)	0.125-30	500	Within 1 hour on 135% rated current. Time lag: Within 10-25 seconds on 500% rated current.
F16 (3" long by 13/16" dia)	35-60	500	Within 1 hour on 135% rated current.
F62 (3" long by 13/16" dia)	35-60	500	Within 1 hour on 135% rated current.

Figure 8-2.—Distribution boxes.

circuits or, in the larger ships, the installation may be equal to that of a fair sized city.

Regardless of the size of the installation, an electrical system consists of a source of power (generators or batteries) and a means of delivering this power from the source to the various loads (lights, motors, and other electrical equipments).

From the main power supply the total electrical load is divided into several feeder circuits and each feeder circuit is further divided into several branch circuits. Each final branch circuit is fused to safely carry only its own load while each feeder is safely fused to carry only the total current of its several branches. This reduces the possibility of one circuit failure interrupting the power for the entire ship. The distribution boxes are illustrated in figure 8-2. The feeder distribution boxes (fig. 8-2,A) and the branch distribution boxes (fig. 8-2,B) contain fuses to protect the various circuits.

The distribution wiring diagram showing the connections that might be used in a ship's lighting system is illustrated in figure 8-3. A ship's installation might have several feeder distribution boxes, each supplying six or more branch circuits through branch distribution boxes.

Fuses F1, F2, and F3 (fig. 8-3) protect the main feeder supply from heavy surges such as short circuits or overloads on the feeder cable. Fuses A-A1 and B-B1 protect branch No. 1. If trouble develops and work is to be done on branch No. 1, switch S1 may be opened to isolate this branch. Branches 2 and 3 are protected and isolated in the same manner by their respective fuses and switches.

BRANCH CIRCUIT TESTS

Usually, receptacles for portable equipment and fans are on branch circuits separate from lighting branch circuits. Test procedures are the same for any branch circuit. Therefore, a description will be given of the steps necessary to (1) locate the defective circuit and (2) follow through on that circuit and find the trouble.

Voltage Testers

The most commonly used voltage tester is the solenoid type shown in figure 8-4. This type of tester has two indicators, one is a plunger type which moves into the coil (against spring tension) of the tester. The distance the plunger is pulled into the coil varies according to the amount of voltage applied to the coil. This tester is designed for operation on 115 to 550 volts AC or 115 to 600 volts DC. In the center of the tester is a neon glow lamp indicator. The glow lamp is used to indicate if the circuit being tested is AC or DC. When the tester is operated on AC, light is produced only during a portion of

SCALL 11493

65.57

Figure 8-3.—Three-phase distribution wiring diagram.

each half-cycle, and both electrodes of the glow lamp are alternately surrounded with a glow. When the tester is operated on DC, light is produced continuously, and only the negative electrode glows. Therefore the tester will indicate polarity on d-c circuits. The test probes are colored red and black and the glow lamp enclosure is labeled red and black as shown in figure 8-4. If while testing a d-c circuit the electrode of the glow lamp on the side labeled black is glowing, this indicates the black probe of the tester is on the negative side of the circuit; likewise the opposite electrode would glow if the red probe of the tester was on the negative side of the circuit.

Prior to being taken from the electric shop to be used on a circuit, a voltage tester must be tested for proper operation on a known voltage source such as the electric shop test panel.

If your voltage tester is inoperative, give it to your division P. O. to be repaired or replaced. The solenoid type voltage tester gives an audible hum and noticable vibration when applied to a source of AC.

It is easy to fall into the habit of assuming that normal voltage is present when you feel the vibration and hear the hum. However, these indications only mean that SOME voltage is present. It is necessary to actually READ the scale to determine the amount of voltage because certain defects will cause less than normal voltage. Unless this is done, you may assume that normal voltage is present when the actual voltage is less than normal. Less than normal voltage on certain tests (shown later) is a definite clue to the location of faults.

A newer type voltage tester now available to the fleet is the multi-frequency type shown in figure 8-5. This tester utilizes electronic circuitry and seven neon glow lamps to indicate voltage, frequency, and polarity. This tester may be used on 60- or 400-cycle a-c, or on d-c.

CCPIT 11494

73.32

Figure 8-4.—Voltage tester.

77.240

Figure 8-5.—Multi-frequency voltage tester.

One or more of three lamps light to indicate the amount of voltage, labeled as 110, 220, or 440 volts. At the same time one of the remaining four labeled lamps lights to distinguish the a-c frequency, whether 60 cycles or 400 cycles, or whether having negative polarity applied to either the tester's "red probe" or its "black probe" when the tested circuit carries d-c.

Never use a lamp in a "pigtail" lamp holder as a voltage tester. Lamps designed for use on low voltage (120 v) may explode when connected across a higher voltage (440 v). In addition, a lamp would only indicate the presence of voltage, not the amont of voltage. Learn to use and rely on standard test equipment.

Locating the Defective Circuit

Assume that, for some reason, several of the lights are not working in a certain compartment. Because several lights are out, it will be reasonable to assume that the voltage supply has been interrupted on one of the branch circuits.

To verify this assumption, you must first locate the distribution box feeding the circuit that is inoperative. Then make sure that the inoperative circuit is not being supplied with voltage. Unless the circuits are identified in the distribution box, you will first need to measure the voltage at the various circuit terminations. For the following procedures, use the circuits shown in figure 8-3 as an example circuit.

To pin down the trouble, connect the voltage tester to the load side of each pair of fuses in the branch distribution box. No voltage between these terminals indicates a blown fuse or a failure in the supply to the distribution box. To find the defective fuse, make certain S1 is closed, then connect the voltage tester across A-A1, and next across B-B1 (fig. 8-3). The full-phase

11495

voltage will appear across an open fuse, provided circuit continuity exists across the branch circuit. However, if there is an open circuit at some other point in the branch circuit, this test is not conclusive. If the load side of a pair of fuses does not have the full-phase voltage across its terminals, place the tester leads on the supply side of the fuses. The full-phase voltage should be present. If the full-phase voltage is not present on the supply side of the fuses, the trouble is in the supply circuit from the feeder distribution box.

Assume that you are testing at terminals A-B (fig. 8-3) and that normal voltage is present. Move the test lead from A to A1. Normal voltage between A1 and B indicates that fuse A-A1 is in good condition. To test fuse B-B1, place the tester leads on A and B, and then move the lead from B to B1. No voltage between these terminals indicates that fuse B-B1 is open. Full-phase voltage between A and B1 indicates that the fuse is good.

This method of locating blown fuses is preferred to the method in which the voltage tester leads are connected across the suspected fuse terminals because the latter may give a false indication if there is an open circuit at some point in the branch circuit.

Testing for Grounds

If no voltage is supplied to the branch circuit, determine the type of circuit: lighting, portable equipment, receptacles, or other. This is necessary to avoid false interpretations of tests made later.

To test for grounds with a megger, find or prepare a spot on the bare metal of the ship's hull to avoid the insulating effect of paint or enamel. This spot should be on a bulkhead or overhead to ensure a good ground. To protect yourself while making tests, leave BOTH fuses out of the holder. Then, close switch S1 in order to make the ends of the circuit accessible inside the cabinet. In addition, if you close the unfused switch, its contacts and internal connections are included in the tests.

Connect one test lead of the megger to the bare spot prepared on the metal and the second test lead to terminal X (fig. 8-3).

A resistance of 1 megohm or more is tolerable and it indicates that the lead from terminal X to the end of the circuit is free from grounds. The next part of the test is to move the test lead from terminal X to terminal Y. The second test lead should remain connected to ground. If the resistance from Y to ground is 1 megohm or more, the lead from Y to the end of the circuit may be considered free from grounds.

If both leads are found to be free from grounds, check for overloading. This might happen if a machine tool had been connected to a circuit that was already near maximum loading. The additional load will cause the fuse to blow. Therefore, move that tool to an underloaded circuit.

Other Trouble Finding Hints

Make it a part of your circuit-testing steps to check if any additional loads were connected when the fuse opened. If you find an overload, it should be removed. If no overload is present, go back to the branch distribution box, open S1, and replace A-A1 and B-B1. Then, close S1. If the fuse does not blow, you can assume that the first fuse failure was due to aging or some other transient effect.

However, if the replacement fuse blows, the overload may be due to a short circuit between conductors, which would not show up in a megger test for grounds. A megger is not suitable for checking low resistance, and it will be necessary to use an ohmmeter (lowest range scale) in making further tests. Because an ohmmeter can be damaged by connecting it in a circuit that is carrying current, open S1 and remove fuses A-A1 and B-B1 before starting the tests. Then close S1 so that it will be included in the tests.

The ohmmeter test leads should be connected to terminals A1 and B1. Zero resistance between these terminals indicates a direct short circuit across the line. However, you should be careful in interpreting the results of this test. For example, consider a case where 10 lamps are connected in parallel.

The number of lamps and the individual wattage of the lamps will determine the circuit resistance measured between A1 and B1. The resistance checked in this manner is the "cold" resistance of the lamp filaments. This resistance is not the same value that you would obtain in an Ohm's law calculation, using rated voltage and power because for this condition the filament is hot, and for tungsten resistance increases as the temperature increases.

For example, the cold resistance of a 40-watt, 120-volt lamp may vary between 40 and 50 ohms; whereas, the hot resistance is of the order of 360 ohms. Ten of these lamps connected in

through a gear train until the null position is reached. When this occurs, the voltage induced in the rotor drops to zero; The output of the amplifier also becomes zero; and since only the excitation winding of the induction motor is energized, the motor stops. The position of the synchro rotor is therefore determined by the position of the fluxgate with respect to the earth's magnetic field; consequently, when the aircraft turns, changing the azimuth relation of the fluxgate to the earth's magnetic field, the synchro rotor and attached indicator pointer are turned by the induction motor through the same angle in the same direction. When the synchro rotor reaches the null position, the master indicator shows the magnetic heading of the aircraft. A transmitting magnesyn, which is also turned by the induction motor, provides controlling voltages for remote-indicating repeaters.

Analysis of Azimuth Stabilization

A simplified schematic of the azimuth stabilization section of the radar that will be used in this analysis is shown in figure 17-32. The MASTER INDICATOR of the fluxgate compass system contains the transmitting synchro used with this azimuth stabilization system. The rotor of the transmitting synchro is mechanically coupled to the shaft that drives the pointer of the master indicator. As the aircraft changes its heading, the rotor correspondingly changes position at a one-to-one ratio. The stator of the transmitting synchro is electrically coupled to the contacts of relay K2101. This relay is energized by the operation of the bearing switch on the control unit of the radar system. By referring to figure 17-32, it can be seen that K2101 must be energized before the output of the transmitting synchro can be utilized in stabilization.

The ZERO SET SYNCHRO is utilized to zero set the PPI sweep position when the output of the transmitting synchro is not used, which is during relative bearing operation. The stabilization system will first be described as it relates to relative bearing operation; later it will be shown how azimuth stabilization is provided when the transmitting synchro of the aircraft compass system is connected to the azimuth followup synchro. When on relative bearing operation, the indicators are nonstabilized and the top of the indicator represents the heading of the aircraft; the targets are displayed with respect to the heading of the aircraft.

Figure 17-32.—Analysis of azimuth stabilization.

The rotors of the zero set synchro and the transmitting synchro of the fluxgate compass are supplied excitation voltage from the same source. The zero set synchro is adjusted manually. Its positioning will be discussed later.

The stator of the AZIMUTH FOLLOWUP SYNCHRO is electrically coupled to either the stator of the transmitting synchro in the fluxgate compass or the stator of the zero set synchro. The stator that is used for coupling depends upon the position of K2101. The rotor of the followup synchro is mechanically connected to the azimuth torque motor and the secondaries of the azimuth sweep synchro. The phase relationship between the rotor of the transmitting synchro or the zero set synchro determines the amplitude and polarity of the signal developed at the rotor of the followup synchro. When, for example, the rotors of the followup and the zero set synchros are 90° displaced, as shown in figure 17-32, there will be no signal at the rotor of the followup synchro. If, however, the

parallel will have a "cold" resistance between 4 and 5 ohms. These low values are difficult to measure unless you use considerable care in setting up the ohmmeter and in reading the indicated value. Unless these precautions are taken, you may easily mistake the normal "cold" resistance of a parallel connected group of lamps for a short circuit.

Assume that your resistance tests have shown a short circuit. How do you locate the trouble?

Although branch No. 1 (fig. 8-3) shows three lamps, an actual circuit may contain more or less than this number. Choose a lamp that appears to be near the center of the affected group and open the housing to expose the leads.

The wire leads are attached to the fixture with screw-type fasteners. The socket shell screws are inserted in metal bars, which serve to connect the lamp socket terminals to the line. Two other screws anchored in the socket insulation serve as feed-through terminals for line wires entering and leaving the outlet box. Therefore, it will be easy to "pair up" the leads for testing. Disconnect each pair of leads from the fixture terminals.

As a safety precaution, when you open a box or outlet, always check for voltage at that location; never assume that the circuit is dead.

It is possible to determine the direction of the fault from the opened outlet box. To do this, connect the ohmmeter to the pair of leads that go back to the distribution box. If the meter indicates a short circuit, the fault is in that direction. If an open circuit is indicated, the ohmmeter leads should be removed and connected to the pair of wires running toward the end of the circuit. Remember to take lamp resistance into account or remove the lamps from the sockets.

If no short circuits show up when you make this test, the short is in the fixture that has been disconnected. The trouble will naturally disappear when the defective fixture is disconnected.

Assuming that your tests at the opened box have shown a fault toward the end of the line, open another outlet box at a point approximately halfway between the first opened outlet box and the end of the line. The leads in the second opened outlet should be disconnected from the fixture. Each pair of wires should be tested for a short circuit. This will show whether the trouble is between the two open boxes or between the second open box and the end of the circuit.

If the trouble is found to be between the two opened outlet boxes, open any boxes between them, disconnect the fixture, and make the tests for short circuits at each box and at the end of the line. Bear in mind that the trouble may be in the cable running between the two boxes. When it is, usually it is necessary to pull in new cable. However, some cables have a spare wire, which might be used to save running a new cable.

On circuits for portable equipment, disconnect each item. If a short circuit disappears, the trouble is in some of the portable equipment. In this case, the defective fuse can be replaced and the circuit energized. If the short remains with the portable equipment disconnected, the circuit should be tested, as described for lamp circuits.

Of course, if the trouble is due to defective portable equipment, each item should be carefully checked before it is reconnected to the line. Any defective equipment should be repaired.

To test a circuit for portable devices, it is sometimes helpful to connect an ohmmeter at the distribution box and watch the meter (or have someone watch it for you) as each portable device is disconnected from the line. If the short circuit disappears when one item is disconnected, assume that this item was the cause of the trouble.

THREE-PHASE FUSED CIRCUITS

The tests previously described relate to individual branch circuit troubles. However, branch circuit faults may not always be confined to an individual branch. Instead, the trouble may be in the feeder distribution system.

For example, assume that you get a report that one-third of the lights in a section or compartment are normal and the remaining two-thirds are dim. Because these lights are on different branch circuits, use the report information to determine possible causes of trouble.

The feeder supply circuit is 3-phase, and the lighting branches are single-phase circuits. The changeover from 3-phase to single-phase is made in the branch distribution box by connecting the various branch circuits to the proper feeders. Figure 8-3 illustrates how these connections are made.

Now, assume that a fuse in the feeder distribution box opens. This fuse will open one leg of the 3-phase supply. When this happens, the loads will then form two branch circuits in series across a single-phase branch circuit. It will be easier to visualize this condition by examining figure 8-6, which is a simplification of the figure shown in figure 8-3.

11497

77.97

Figure 8-6.—Simplified main and branch wiring.

In this circuit, consider that fuse F1 is open. Branch circuit 3 still has normal connections to phase B-C. Therefore, it will receive normal voltage, and all lamps on this circuit will light to normal brilliancy. However, because of the open fuse, F1, branches 1 and 2 cannot receive normal voltage. They do, however, receive voltage from terminals B and C. The supply path is from terminal B through fuse F2, branch 1 to branch 2, to fuse F3 and terminal C. Therefore, branches 1 and 2 are in series across the terminals (E and G in fig. 8-6) that supply branch 3.

If the wattages of the series-connected lamps are equal, the voltages will divide equally across each load, and lights connected in these circuits will light to about half brilliancy. However, any load unbalance will cause unequal voltage division in the branch circuits so that, in an actual case, there may be several degrees of lamp brilliance in lighting circuits connected to the same distribution box.

The same action will be noted if fuse F3 opens, except that branch 1 will have normal voltage, and the voltage of this branch will divide across branches 2 and 3 because they will be in series across the supply voltage.

If fuse F2 opens, branch 2 will receive normal voltage, and branches 1 and 3 will be in series across the voltage supply.

Thus, you can see that an open fuse in any leg of the 3-phase supply mains will give an immediate indication as to the cause of the trouble. In this example, the first clue is the dimming of lights on some circuits and full brilliance of lights on others. Suspicions of an open-phase fuse can then be confirmed by voltage measurements.

Voltage Tests

At the feeder distribution box (fig. 8-3) determine which fuse is defective. To do this, connect the test leads of the voltage tester across fuse F1. If the fuse is open (fig. 8-6), the full voltage of that phase will be indicated by the tester, provided circuit continuity is maintained through connected loads in branches 1, 2, and 3. If the fuse is in good condition, it will shunt the voltage indicator, and no voltage will be shown.

There is, however, an exception to this test. If an open circuit is at another point in that circuit, no voltage will appear across an open fuse. However, this condition is not likely to exist in tests at the feeder distribution box because of the relatively large number of connected loads compared with the number of loads at the distribution box (fig. 8-6).

Open-Circuit Tests

If fuse F1 is open and branches 1 and 2 are in good condition and located, the full voltage will appear across the open fuse (fig. 8-6). If an overload on branch 1 has caused fuses A-A1 and F1 to open, a test across F1 will show full voltage because of a path through branch 2 and its associated fuses.

If F1 and D-D1 open but A-A1 stay closed, the path will be completed through branch 1 and its fuses.

Assuming there is no burned, cut, faulty, or other open wire in the system the only other condition that prevents voltage across an open feeder distribution fuse is simultaneous open circuits in two branch circuits.

Simultaneous open circuits in branches 1 and 3 will prevent voltage from appearing across the open fuse F2. No voltage will appear across the open fuse F3, if branches 2 and 3 open simultaneously.

Kirchoff's law states that, in a series circuit, the full source voltage will appear across an open circuit. No voltage drop will appear across any load resistance in the circuit because no current can flow in an open circuit. In order

11438

for a voltage drop to appear across a resistance (load), current must be flowing in the circuit.

If only one branch circuit is interrupted, it is safe to assume that the feeder distribution box fuses are in good condition and that a fuse is blown in the branch distribution box. However, do not overlook the necessity for actually measuring voltage. As mentioned before, do not mistake vibration or hum in the voltage tester as an indication that normal voltage is present.

If two branch circuits are affected but each branch has some voltage, check the feeder distribution box fuses.

As another example, you might find that all lights on branch 1 (fig. 8-3) are out. First, try to decide which parts, if defective, will open the circuit.

If S1 is open, it is obvious that the lights will be out. If the switch is in the OFF position, the trouble is readily apparent, and the cure is to turn the switch ON. However, if the switch is in the ON position but open circuited because of an internal defect, the trouble will not be apparent through a visual examination.

Another cause of circuit failure could be a blown fuse, A-A1 or B-B1. They should be tested as described for branch circuit tests.

If these tests prove that fuses A-A1 and B-B1 are in good condition, the open circuit will be between the fuses and the first light on the circuit. If it were at some other point, one or more of the lights on the circuit would be operating.

Check the switch by removing the front of the distribution box so that terminals X1 and Y1 are exposed (fig. 8-3). The switch wafer can be turned to the ON position with a screwdriver. The voltage tester leads should be connected to X1-Y1. No voltage means one or both switch arms are open. To check, connect your voltage tester to X-Y. This phase voltage should be present. Leave one lead on X and move the other lead to Y1. Normal line voltage between these points is an indication that switch arm Y-Y1 is in good condition. No voltage means that the switch arm or contacts are defective, and the switch should be replaced. Arm X-X1 is tested by placing one test lead on Y and the other on X1.

If the switch is in good condition and voltage is present at X1-Y1, the open circuit is between X1-Y1 and the first light.

The foregoing discussion shows that the effect is a clue to the type of trouble. If only one circuit is out of commission, look for a blown fuse in the branch distribution box. If one circuit is normal and two other circuits have less than full voltage, look for a blown fuse in the feeder distribution box.

When operated electrically, the operation is usually in conjunction with a pilot device such as a relay or switch. Electrically operated circuit breakers employ an electromagnet, used as a solenoid, to trip a release mechanism that causes the breaker contacts to open. The energy to open the breaker is derived from a coiled spring. The electromagnet is controlled by the contacts in the pilot device.

CIRCUIT BREAKERS

Circuit breakers have three fundamental purposes: First, they are used to provide circuit protection and to perform normal switching operations. Second, they are used to isolate a defective circuit while repairs are being made. Third, circuit breakers are used in manual and automatic bus transfer, also as starters for large motors.

Air circuit breakers are used in switchboards, switch gear groups, and in distribution panels. The types installed on naval ships are ACB, AQB, AQB-A, AQB-LF, NQB-A, ALB and NLB. They are called air circuit breakers because the main current carrying contacts interrupt in air.

Circuit breakers are available in manually or electrically operated types. Some types may be operated both ways, while others are restricted to one mode. Manually or electrically operated types may or may not provide protective functions; the following sections describe the differences and uses of the various types of circuit breakers.

ACB

The ACB type of circuit breaker may be for either manual local closing or electrical remote closing. It has an open metallic frame construction mounted on a drawout mechanism and is normally applied where heavy loads and high short circuit currents are available.

Figure 8-7 shows the external appearance of a type ACB circuit breaker.

Type ACB circuit breakers are used to connect ship's service and emergency generators to the power distribution system. They are also

11499

27.73

Figure 8-7.—Type ACB circuit breaker.

used on bus ties and shore connection circuits, and on some feeder circuits from the ship's service switchboard.

When used in these applications the pilot device may be a reverse-power relay or any of the control devices discussed later in this chapter of the training manual. The reverse-power relay is mounted on the panel close to the circuit breaker. Other automatic controls may be located at remote points to give maxmum protection to the circuit.

Circuit breakers designed for high currents have a double-contact arrangement. The complete contact assembly consists of the main bridging contacts and the arcing contacts. All current carrying contacts are high-conductivity, arc-resisting silver or silver alloy inserts.

Each contact assembly has a means of holding the arcing to a minimum and extinguishing the arc as soon as possible. The arc control section is called an arc chute or arc runner. The contacts are so arranged that when the circuit is closed, the arcing contacts close first. Proper pressure is maintained by springs to ensure the arc contacts close first. The main contacts then close.

When the circuit opens, the main contacts open first. The current is then flowing through the arc contacts, which prevents burning of the main contacts. When the arc contacts open, they pass under the front of the arc runner. This causes a magnetic field to be set up, which blows the arc up into the arc quencher and quickly opens the circuit.

Type ACB circuit breakers are divided into manually and electrically operated types. The only difference is that the manually operated types must be operated by hand. However, all ACB circuit breakers may be operated electrically if the magnet and armature mechanism is installed. The heavy-duty types are electrically operated because it is then unnecessary for personnel to approach them in order to open or close the circuit.

No circuit breaker, regardless of type, should be worked on without opening the circuit. Remember that certain terminals may have voltage applied to them even though the breaker is open.

AQB

Type AQB circuit breakers are mounted in supporting and enclosing housings of insulating material and have direct-acting automatic tripping devices. They are used to protect single-load circuits and all feeder circuits coming from a load center distribution panel.

Where the requirements are low enough, the type AQB may be used on generator switchboards. Figure 8-8 illustrates one of the older type AQB breakers. This type of circuit breaker is being replaced by a newer AQB-A type breaker as repair becomes necessary since these circuit breakers and their repair parts are no longer being manufactured. In accordance with BuShips Inst 9620.78 of 21 February 1966, Navy type AQB circuit breakers, specifically Westinghouse type ABN and General Electric type AF-IN are obsolete types. Many older type ships such as the DD-445 class and World War II type DE's still use these now obsolete breakers. When it becomes necessary to repair or replace one of the obsolete type circuit breakers, it should be replaced by the newer AQB-A101, AQB-A250, AQB-A400, or AQB-A800 as required.

AQB-A250

The newer AQB type circuit breakers such as the AQB-A250 in figure 8-9 have several advantages over the older type shown in figure 8-8.

27.74

Figure 8-8.—Type AQB circuit breaker.

77.241

Figure 8-9.—AQB-A250 circuit breaker complete, front view.

The outside dimensions of these new breakers are the same for both the two-pole and three-pole circuit breakers. They are designed for front or rear connections as required and may be mounted so as to be removable from the front without removing the circuit breaker cover. The voltage ratings of the AQB-A250 are 500 volts AC, 60 cycles, or 250 volts DC.

The 250 part of the circuit breaker type designation indicates the frame size of the circuit breaker. When we say a 250 ampere frame size circuit breaker, this means the current carrying parts of the breaker have a continuous rating of 250 amperes. Trip units (fig. 8-10) for this breaker are available with current ratings of 125, 150, 175, 225 and 250 amperes.

The trip unit houses the electrical tripping mechanisms, the thermal element for tripping the circuit breaker on overload conditions, and the instantaneous trip for tripping on short circuit conditions.

In addition 100, 160, and 250 ampere rating trip units with a special calibration are available for use with generator circuit breakers. Regardless of the trip unit used the breaker is still a 250 ampere frame size. The automatic trip devices of the AQB-A250 circuit breaker are "trip free" of the operating handle; in other words the circuit breaker cannot be held closed by the operating handle if an overload exists. When the circuit breaker has tripped due to overload or short circuit, the handle rests in a center position. To reclose after automatic tripping, move the handle to the extreme OFF position which resets the latch in the trip unit, then move the handle to the ON position.

The AQB-A250 circuit breaker may have auxiliary switches, shunt trip (for remote tripping), or undervoltage release attachments when so specified. However, a shunt trip cannot be provided in the same breaker with an undervoltage release. Figure 8-11 shows a trip unit with shunt trip and figure 8-12 shows a trip unit with undervoltage trip. The coil for a shunt trip has a dual rating for a-c and d-c voltages whereas the undervoltage trip coils are wound for a specified voltage such as 450 a-c or 250 d-c and have rated pick-up and drop-out values. The instantaneous trip setting of the AQB-A250 trip units may be adjusted by the instantaneous trip adjusting wheels shown in figure 8-10.

Though not shown in the figure these trip adjusting wheels are marked for five positions, LO-2-3-4-HI, the trip unit label (not shown) will list the instantaneous trip value obtainable for each marked position. Identical settings must be made on each pole of the circuit breaker. NEVER remove a circuit breaker cover to perform adjustments while the circuit breaker is in the closed (ON) position.

Terminal mounting block assemblies used in conjunction with the circuit breaker (fig. 8-13) for drawout mounting, consist of terminal studs in terminal mounting blocks of insulating material. The terminals of the circuit breaker have slip type connectors which engage the terminal studs as shown in figure 8-13. Two mounting blocks are usually required for each circuit breaker. This method of connecting a circuit breaker to a bus or circuit is known as a "back connected circuit breaker." Circuit breakers which have solderless connectors attached to their terminal are commonly called

NAVSHIPS 1703

"front connected circuit breakers". The interrupting rating of the AQB-A250 circuit breaker is 20,000 amperes at 500 volts a-c or 15,000 amperes at 250 volts d-c.

AQB-LF 250

The AQB-LF250 circuit breaker (fig. 8-14), combines the standard ABQ circuit breaker and a current limiting fuse unit which interrupts the circuit when the current is in excess of the interrupting rating of the breaker. Constructed as one compact unit, the AQB-LF circuit breaker incorporates the current limiting fuses (fig. 8-15) as integral parts of the circuit breaker. The common trip features of the AQB-A250 circuit breaker are retained and trip units from 125 to 250 amperes and available for use in the AQB-LF250.

The current limiting fuse unit is designed so that it trips the breaker and opens all poles if any current limiting fuse (fig. 8-16) is blown. After a fuse has blown, the circuit breaker Fig. 8-16 cannot be reclosed until the blown fuse is replaced. Any attempt to remove the fuse unit when the circuit breaker is in the closed position will automatically trip the breaker.

The AQB-LF250 circuit breaker is interchangeable with the AQB-A250 circuit breaker except a larger cutout is required in the switchboard front panel to accommodate the fuse unit of the AQB-LF250.

The AQB-LF250 circuit breaker is a 250 ampere frame size, however the circuit breaker has an interrupting rating of 100,000 amperes at 500 volts a-c whereas the AQB-A250 circuit breakers interrupting rating is 20,000 amperes at 500 volts a-c.

While the AQB-A250 circuit breaker could be either front or back connected, the AQB-LF250 is designed only for back (drawout type) connection, using the same type of slip connectors and terminal studs as shown in figure 8-13.

NQB-A250

The NQB-A250 circuit breaker (fig. 8-17) is similar to the AQB-A250 circuit breaker except the NQB-A250 has no automatic tripping devices. This type of circuit breaker is used for circuit isolation and manual transfer applications. This NQB-A250 is still a 250 ampere frame size as the current carrying parts of the breaker are capable of carrying 250 amperes. Technically this circuit breaker is simply a large ON and and OFF switch. Some types of AQB and NQB breakers are provided with electrical operators mounted on the front of the breaker. These are simply solenoids for remote operation of the breaker handle.

ALB

Type ALB circuit breakers are designated low-voltage, automatic circuit breakers. The continuous duty rating ranges from 5 through 200 amperes at 120 volts a-c or d-c. The breaker is provided with a molded enclosure, drawout type connectors, and nonremoveable and nonadjustable thermal trip elements.

This circuit breaker is a quick-made, quick-break type. If the operating handle is in the tripped (midway between ON and OFF) position, indicating a short circuit or overload, the operating handle must be moved to the extreme off position, which automatically resets the overload unit and the breaker can again be closed.

NLB

Circuit breakers type NLB are small and are used on low voltage systems (24 v d-c, 120 v d-c, and 120 v a-c). They have no automatic tripping device and are used only as switches for circuit isolation.

SELECTIVE TRIPPING

The purpose of selective tripping is to isolate the faulty section of the system and at the same time to maintain power on as much of the system as possible. Selective tripping of circuit breakers is obtained by coordination of the time-current characteristic of the protective devices so that the breaker closest to the fault will open first, and the breaker farthest from the fault and closest to the generator will open last.

Tripping Facilities

A portion of a distribution system with circuit breakers employing selective tripping is illustrated in figure 8-18,A. The tripping time characterisitics are indicated in figure 8-18,B. The so-called instantaneous tripping time is the minimum time required for a breaker to open and clear a circuit when the operation of the breaker is not intentionally delayed.

90071505

zero set rotor is turned 10°, an error signal will be introduced into the rotor of the azimuth followup synchro. The amplitude of the error signal produced will be dependent upon the amount of displacement between the rotors. The polarity or phase of the signal will depend upon the direction of displacement. The error signal is fed to the servoamplifier input of the true bearing amplifier which drives the azimuth torque motor.

The AZIMUTH TORQUE MOTOR is a 2-phase induction type motor. The fixed voltage winding of this motor is connected to the same power source that supplies the rotors of the transmitting and the zero set synchros. The control winding is connected to the output of the true bearing amplifier. The amplitude and phase of the error signal applied to the control windings depend upon the amount and direction of displacement of either of the two exciting rotors (zero set or transmitter). The azimuth torque motor turns in a direction that is determined by the phase relationship of the voltages applied to these two windings. Since the torque motor is mechanically coupled to the azimuth followup synchro rotor and as the motor turns, it drives the followup rotor to a new null relationship with the rotor of the zero set synchro. As the rotors once again approach their 90° relationship, the amplitude of the error signal decreases, thus decreasing the amplitude of the voltage applied to the control winding of the torque motor. When the rotors of the zero set and the followup synchros are once again displaced by 90°, there is no longer a signal applied to the control winding and the torque motor stops. As previously stated, the azimuth torque motor also turns the secondaries of the azimuth sweep synchros; thus, shifting the position of the azimuth sweep secondaries changes the position of the sweep on the indicators. For example, assume that the antenna is in a dead ahead position, with the sweep pointing to the top of the indicator. Then, by adjusting the zero set synchro to a setting of 10°, which shifts the sweep secondaries by 10°, the sweep position would move to 10°.

The primary (rotor) of the azimuth sweep synchro is mechanically coupled to the antenna; thus, when the antenna rotates, the primary winding is also rotated. The primary winding is supplied with sweep voltages from the radar synchronizer. These voltages are induced into the secondary coils with a variation of phase and amplitude for each coil, depending upon its instantaneous angular relationship with the primary. The secondary voltages are applied to the vertical and horizontal coils of the PPI indicator. By means of these voltages, the angular deflection of the sweep trace on the PPI indicator is controlled in accordance with the instantaneous azimuth position of the radar antenna.

The example cited previously utilized the movement of the zero set synchro (manual adjustment) to move the secondaries of the azimuth sweep synchro and hence the PPI sweep. The same comparison may be made with the transmitting synchro. This synchro changes as the heading of the aircraft changes, and this action coupled with the operation of the system just discussed is the analysis of azimuth stabilization.

Comparison of the True and Relative Bearings

As already explained, changing the aircraft heading changes the positions of the sweep secondaries of the azimuth sweep synchro. This occurs on azimuth stabilization only and the change is automatic. On manual operation the only change that can be made is by varying the position of the zero set synchro. This is not stabilization, for it has no relationship to the movement of the aircraft. The zero set synchro is adjusted on manual or relative bearing operation. The antenna is set on 0° with respect to the aircraft and the zero set synchro is adjusted until the sweep appears at the dead ahead position.

During relative bearing operation, with the azimuth indicating device at the top of the scope, and targets appearing thereon, a change in the bearing of the aircraft will result in a change of position of targets. This is an undesirable feature due to the fact that during the time the targets are shifting position they are hard to observe on the indicators. Refer to figure 17-33 for a visual explanation of this condition. The top of the scope indicates the heading of the aircraft and all targets are displayed relative to this heading; thus, on relative bearing operation, the top of the indicator indicates the heading of the aircraft. In other words, when the aircraft is heading north, the top of the scope is north. When the aircraft is heading in any particular direction, the top of the scope is also that direction.

77.249

Figure 8-17.—NQB-A250 circuit breaker front view, cover removed.

Each circuit breaker will trip in less than 0.1 second (almost instantaneously) when the current exceeds the instantaneous trip current setting of the breaker. The individual breakers in a group (generator breakers, bus tie breakers, feeder breakers, etc.) may differ slightly with each other because it is necessary to allow some tolerance in the adjustment, but all breakers in the group will have characteristics that fall within the band. The band is the relation between current and tripping time for a group of circuit breakers that have the same nominal setting.

Generator circuit breakers are usually set to trip instantaneously at a current that is GREATER than the short circuit current of

11507

77.98

Figure 8-18.—Selective tripping of circuit breakers.

11508

the generator, and therefore will not trip instaneously on the generator short circuit current. However, it will trip on the generator short circuit current at some definite interval of time within the tolerance of the breaker (points P_1 to P).

Bus tie circuit breakers are usually set to trip after a prescribed time dalay (which is less than the generator circuit breaker time delay), at a current that is nearest to, but not less than 150% of the bus tie breaker coil rating (for multigenerator switchgear groups) or the nearest to but not more than 80% of the generator breaker short-time delay setting (for single generator switchgear groups). Instantaneous tripping is not normally used on bus tie circuit breakers.

The construction of circuit breakers for selective tripping, for currents less than the instantaneous trip current setting, is such as to cause an intentional delay in the operation of the breaker. The time delay is greater for small currents than for large currents and is therefore known as an inverse time delay. The current that would trip the AQB load circuit breaker instantaneously and clear the circuit will not trip the ACB feeder circuit breaker unless the current flows for a greater length of time. The same sequence of operation occurs for the other groups of circuit breakers adjusted for selective tripping in the system. The difference between the tripping times of the breakers is sufficient to permit each breaker to trip and clear the circuit before the next breaker starts to operate.

Assume that a fault or defect develops in the cable insulation at point A (fig. 8-18,A) and allows an overcurrent I (fig. 8-18,B) to flow through the AQB load circuit breaker and the ACB feeder circuit breaker. The AQB load breaker will open the circuit and interrupt the current in an interval of time, T, that is less than the time, T1, required to open the ACB feeder circuit breaker. Thus, the ACB feeder breaker will remain closed when the AQB breaker clears the circuit. However, if the fault current should exceed the interrupting capacity of the AQB load breaker (for example, an excess of 10,000 amperes), this breaker would be unable to interrupt the fault current without damage to the breaker. To prevent damage to the AQB load breaker, the ACB feeder breaker (on switchboard 1S) serves as a BACK UP breaker for the AQB load breaker and will open almost instantaneously in time, T.

A fault at point B with overcurrent I would trip the ACB feeder breaker in time T1 but not the ACB generator or bus tie breakers, which require longer time intervals, T3 and T2 respectively, in which to trip. A fault at point C with overcurrent I would trip both ACB bus tie breakers at time T2. A fault at D with overcurrent I on switchboard 1S would trip the associated ACB generator breaker in time T3 and one or both of the ACB bus tie breakers in time T2. In each case, the faulty section of the system is isolated, but power is maintained on as much of the system as possible with respect to the location of the fault.

The attainment of selective tripping requires careful coordination of the time-current characteristics for the different groups of circuit breakers. For example, if the system illustrated in figure 8-18 is operating split plant (bus ties open) and if the time-current characteristics of the ACB feeder breaker and the ACB generator breaker were interchanged, a fault at B with overcurrent I would trip generator 1SG off the line in time T1 but would leave the feeder connected to the switchboard (the time required to trip the ACB feeder breaker would be T3). This action would disconnect power to all equipment supplied by switchboard 1S and also would not isolate the faulty section. Therefore, no unauthorized changes should be made to circuit breaker trip settings because these changes may completely disrupt the scheme of protection based on selective tripping. The adjustments for selective tripping of the circuit breakers are made and sealed at the factory.

It is not feasible to provide system protection by selective tripping of circuit breakers in all types of naval ships or for all circuits. For example, d-c distribution systems in older ships and all lighting circuits use fuses to a great extent. Time delay can be incorporated only to the extent that is permitted by the characteristics of the fuses. The use of progressively large fuse sizes from the load to the generator provide some degree of selectivity for overload or limited fault protection.

MAINTENANCE

Metal locking devices are available that can be attached to the handles of AQB type circuit breakers to prevent accidental operation. All breaker handles are now provided with a 3/32" hole permitting fastening the locking device with a standard cotter pin. NavShips Technical

11509

Manual, Chapter 9600, lists the stock numbers for three different sizes of breakers.

Circuit breakers require careful inspection and cleaning at least once a year (more frequently if subjected to unusually severe service conditions). The special inspections follow.

No work shall be undertaken on circuit breakers without first obtaining approval of the electrical or engineer officer. See article 60-37(10) in NavShips Technical Manual. Be very certain you understand and follow every requirement outlined in articles 60-35 through 60-46 of that technical manual. These vital safety regulations shall be enforced.

Before working on a circuit breaker be aware of its time delay characteristics, whether short time, long time, or instantaneous tripping-time is required. The adjustments that produce selective tripping of the circuit breakers are made and sealed at the factory; no unauthorized changes should be made to their trip settings because these changes may completely disrupt their intended functions of protection. Improper tripping action is corrected best by replacement of the entire breaker assembly, especially where trouble is encountered in the compact assemblies.

A special inspection should be carefully made of each pair of contacts after a circuit breaker has opened on a heavy short circuit. Before working on a circuit breaker, deenergize all control circuits to which it is connected; the procedure differs somewhat with the type of mounting which is employed. For example, before work is performed on drawout circuit breakers, they should be switched to the open position and removed. Before working on fixed-mounted circuit breakers, open the disconnecting switches ahead of the breakers. If disconnecting switches are not provided for isolating fixed-mounted circuit breakers, deenergize the supply bus to the circuit breaker, if practicable, before inspecting, adjusting, replacing parts, or doing any work on the circuit breaker.

Contacts are the small metal parts especially selected to resist deterioration and wear from the inherent arcing. The arcing occurs in a circuit breaker while its contacts are opening and carrying current at the same time. When firmly closed, the contacts must not arc.

Contact materials have been subjected to constant research, resulting in various products, ranging from pure carbon or copper, to pure silver, each being used alone and also as alloys with other substances. Modern circuit breakers have contacts made of pure silver, or pure silver mixed with cadmium oxide, or pure silver and tungsten. The two latter silver alloys are extremely hard and resist being filed. Fortunately, such contacts made of silver or its alloys conduct current when discolored (blackened during arcing) with silver oxide. The blackened condition, therefore, requires no filing, polishing, or removal. As with a pure silver contact, silver oxide is formed during arcing and it has been found that the addition of cadmium oxide greatly improves operation of the contact because it minimizes the tendency of one contact to weld to another, retards heavy transfer of one material to another, and inhibits erosion.

Usually, a contact containing silver is serviceable as long as the total thickness worn away is on the order of 0.015 to 0.030 inch.

Severe pitting or burning of a silver contact is another matter. It may require some filing (with a fine file or with fine sandpaper, No. 00) to remove raised places on surfaces that prevent intimate and overall closure of the contact surfaces. If necessary, use a CLEAN cloth moistened with INHIBITED methyl chloroform. Be very certain to provide ample ventilation to remove all DEADLY and TOXIC fumes of the solvent.

When cleaning and dressing copper contacts, maintain the original shape of each contact surface and remove as little copper metal as possible. Inspect and wipe the copper contact surfaces for removal of the black copper-oxide film and, in extreme cases, dress and clean only with fine (No. 00) sandpaper to prevent scratching the surfaces. (To avoid scratches, NEVER use emery cloth or emery paper.) Because this copper-oxide film is a partial insulator, follow the sanding procedure by wiping with a clean cloth moistened with inhibited methyl chloroform solvent. Provide VERY LIBERAL ventilation by means of exhaust fans or with portable blowers to entirely remove all traces of the deadly fumes of the solvent.

Calibration problems on circuit breakers should be handled in accordance with chapter 9600 of NavShips Technical Manual.

The function of arcing contacts is not necessarily impaired by surface roughness. Remove excessively rough spots with a fine file. Replace arcing contacts when they have been burned severely and cannot be properly adjusted. Make a contact impression and check the spring pressure in accordance with the

C02H1510

manufacturers' instructions. If information on the correct contact pressure is not available, the contact pressure should be checked with that of similar contacts. When the force is less than the designed value, the contacts either require replacing because they are worn down, or the contact springs should be replaced. Always replace contacts in sets; not singly, and replace contact screws at the same time. Do not use emery paper or emery cloth to clean contacts, and do not clean contacts when the equipment is energized.

Clean all surfaces of the circuit breaker mechanism, particularly the insulation surfaces, with a dry cloth or air hose. Before directing the air on the breaker, be certain that the water is blown out of the hose, that the air is dry, and that the pressure is not over 30 psi. Check the pins, bearings, latches, and all contact and mechanism springs for excessive wear or corrosion and evidence of overheating. Replace parts if necessary.

Slowly open and close circuit breakers manually a few times to be certain that trip shafts, toggle linkages, latches, and all other mechanical parts operate freely and without binding. Be certain that the arcing contacts make before and break after the main contacts. If poor alignment, sluggishness, or other abnormal conditions are noted, adjust in accordance with the manufacturer's instructions for the particular circuit breaker.

Oil-piston type overcurrent tripping devices (grade B timers) are sealed mechanisms and normally do not require any attention. When oil-film (dashpot) overcurrent tripping devices are used, the oil should be removed and the interior of the oil chambers should be cleaned with kerosene and refilled with new oil every six months. Be certain that the dashpot is free of dirt, which destroys the time-delay effect, and that the tripping device is clean, operates freely, and has sufficient travel to trip the breaker. Do not change the air-gap setting of the moving armature because this would alter the calibration of the tripping device. Lubricate the bearing points and bearing surfaces (including latches) with a drop or two of light machine oil. Wipe off any excess oil.

Before returning a circuit breaker to service, inspect all mechanical and electrical connections, including mounting bolts and screws, drawout disconnect devices, and control wiring. Tighten where necessary. Give the breaker a final cleaning with a cloth or compressed air. Operate manually to be certain that all moving parts function freely. Check the insulation resistance.

The sealing surfaces of circuit-breaker contactor and relay magnets should be kept clean and free from rust. Rust on the sealing surface decreases the contact force and may result in overheating of the contact tips. Loud humming or chattering will frequently warn of this condition. A light machine oil wiped sparingly on the sealing surfaces of the contactor magnet will aid in preventing rust.

Oil should always be used sparingly on circuit breakers, contactors, motor controllers, relays, and other control equipment, and should not be used at all unless called for in the manufacturer's instructions or unless oil holes are provided. If working surfaces or bearings show signs of rust, disassemble the device and carefully clean the rusted surfaces. Light oil can be wiped on sparingly to prevent further rusting. Oil has a tendency to accumulate dust and grit, which may cause unsatisfactory operation of the device, particularly if the device is delicately balanced.

Arc chutes or boxes should be cleaned by scraping with a file if wiping with a cloth is not sufficient. Replace or provide new linings when they are broken or burned too deeply. Be certain that arc chutes are securely fastened and that there is sufficient clearance to ensure that no interference occurs when the switch or contact is opened or closed.

Shunts and flexible connectors, which are flexed by the motion of moving parts, should be replaced when worn, broken, or frayed.

Operating tests that consist of operating the circuit breakers in the manner in which they are intended to function in service should be conducted regularly. For manually operated circuit breakers, simply open and close the breaker to check the mechanical operation. To check both the mechanical operation and the control wiring, electrically operated circuit breakers should be tested by means of the operating switch or control. Exercise care not to disrupt any electric power supply that is vital to the operation of the ship, or to endanger personnel by inadvertently starting motors and energizing equipment under repair.

OVERLOAD DEVICES

A prolonged overloaded electrical system can be damaged beyond repair by the resulting heat

Staff 11511

and flame. Therefore, it is expedient to use a device which can detect an overload before damage occurs, that either warns the EM of the hazardous condition or automatically turns off the power. Relays have been designed (for both d-c and a-c systems) which are capable of accomplishing these protective functions. The basic difference between a-c and d-c relays is in the armature and magnet core construction.

MAGNETIC TYPE

A magnetic type overload relay for a d-c system is illustrated in figure 8-19. A pictorial view and a diagram identifying the various parts are shown in figure 9-19, A and B respectively.

In an installation, the operating (series) coil ⑥ is connected in series with the protected circuit (fig. 8-19,B). Normal current through the coil will have no effect on relay operation. If an overload occurs, increased current will flow through the coil and cause an increase in the magnetic flux around the coil. When the flux becomes great enough, the iron plunger ⑤ will be lifted into the center of the coil, opening contacts ⑨ and ⑩. This action opens the control circuit to the main contactor in series with the motor terminals, thereby disconnecting the motor from the line.

To keep the relay from operating when the motor is drawing a heavy but normal starting current, an oil dashpot mechanism ① and ② is built in. This gives a time delay action that is inversely proportional to the amount of overload.

Overload relays may use either single or double coils. In addition, the single-coil overload relay may be obtained with or without a manual "latching" control. Relays with manual

11512

latching are used on three-wire controls and reset automatically after an overload has occurred. Double-coil overload relays are used for two-wire control. They have a series coil ⑥ carrying the load current and a shunt holding coil ⑦ mounted above the series coil. These two coils are connected so that their respective fields aid each other. Then, when an overload occurs the plunger moves up into the shunt-connected coil field and is held in the tripped position until the shunt coil is deenergized by the pressing of a reset button or some other form of contact (switch) device.

Before placing the overload relay in service, raise the indicating plate ③ to allow the dashpot ① to be unscrewed from the relay. Lift out the plunger ⑤ and make certain all of the internal parts are clean. Place about 9/16 of an inch of dashpot oil (furnished with the relay) in the dashpot. Replace the plunger and indicating plate, and then screw the dashpot on the relay to the desired setting.

The relay is calibrated at the factory for the individual application, and the current values for which it is calibrated are stamped on the calibration plate ④. The marked values are minimum, maximum, and midpoint currents.

The operating points may be set by first raising the indicating plate ③ which allows the dashpot to be turned. Then, to lower the tripping current, raise the dashpot by turning it. This action raises the plunger further into the magnetic circuit of the relay so that a lower current will trip the relay.

The current at which the relay trips may be increased by turning the dashpot in a reverse direction. This action reduces the magnetic pull on the plunger and requires more current to trip the relay. After the desired settings have been obtained, lower the indicating plate over the hexagonal portion of the dashpot to again indicate the tripping current and lock the dashpot in position.

Figure 8-20 shows two magnetic types of a-c overload relays. Part A is the nonlatching type, and part B is the latching type. In part C the various components are identified.

The operating (series) coil ⑥ is connected in series with the protected circuit (fig. 8-20,C). Therefore, the load current flows through the coil. If the circuit current rises above normal because of overload conditions, it will cause an increase in the magnetic lines of flux about the coil. The increased flux lifts the iron plunger ⑤ into the center of the coil and opens the contacts ⑨. This, in turn, causes the main contactor (not shown) to open, and disconnects the motor or other device from the line. An oil dashpot mechanism ① and ② is used to prevent the operation of the relay on motor starting current surges.

If the relay does not have manual latching, a three-wire control is provided to give automatic reset after an overload occurs. The manual-latch relay is generally used with two-wire control. The latch ⑦ holds the contacts

in the open position after an overload has occurred and the circuits have been deenergized. It is necessary for the operator to manually reset the overload relay at the controller.

THERMAL TYPE

Thermal type overload relays (a-c and d-c) are designed to open a circuit when excessive current causes the heater coils to reach the temperature at which the ratchet mechanism releases. The heater coils are connected in series with the supply line to the load, and normal circuit current will have no effect on them.

The essential operating parts of a d-c thermal overload relay (fig. 8-21) are the two heater coils ④, two solder tube assemblies ⑤, and control contacts ①. Under normal conditions the splitter arm ⑦ (so called because it splits the contacts) completes a circuit with the contacts. The spring is then under compression and the operating arm ③ tends to rotate the splitter arm out of the circuit. This action is prevented by the ratchet assembly, which is held by the solder film between the outer and inner part of the solder tubes.

2. Screw
3. Operating arm
4. Heater coil
5. Solder tube
6. Screw
7. Splitter arm

77.101

Figure 8-21.—Thermal overload relay.

When current flows through the heater coils and produces enough heat to melt the solder film, the inner part of the solder tube assembly rotates and releases the ratchet mechanism to open the control circuits. When this happens, the circuit to the coil handling the power contacts (not shown in the figure) opens and disconnects the load. As soon as the load is disconnected, the heaters cool, and the solder film hardens. When the hardening is complete, the relay is ready to be reset with the rest button.

An adjustable type thermal relay with magnetic reset is illustrated in figure 8-22. This relay may be adjusted to trip at a value between 90 and 110 percent of the rated coil current. To change the operating point, loosen the binding screws that hold the relay heater coil ④ (fig. 8-21) so that the coil position may be changed. Moving the coil away from the relay will increase the amount of current needed to trip the relay. Moving the coil closer to the relay will decrease the current needed to trip the relay. This range of adjustment is available only within the range of 90 to 110 percent of coil rating. Each rating has a different manufacture part number. The correct rating is installed when the controller is installed in the ship. Do not use another rating. Make sure both heater coils in each overload relay are the same rating.

The terminal plates and the underside of the slotted brackets of the heater coil assembly are serrated so that the coil is securely held in position when the binding screws are tightened. Some thermal overload relays have reset magnet assemblies attached. It may become necessary to replace the heater coils from the relay. Then remove the four screws that hold the overload relay to the mounting plate. When removing the relay from the mounting plate, use care not to lose the phenolic pin and bearing block located between the thermal blocks on the underside of the relay.

Next, remove the four large countersunk screws that hold the mounting plate and the reset magnet assembly to the square posts. Remove the four screws in the mounting plate, which support the reset magnet. Take care not to lose the lever and spring, items ⑧ and ⑨. Remove the two screws ⑪ and pull out the plunger guides. Remove the old coil ⑩ and install the new coil. Then insert the plunger

guides and replace the screws (11). Reassemble the magnet, spring, and lever to the mounting plate. Mount the plate on the posts and then mount the overload relay on the mounting plate. Replace the heater coils as the last operation.

Overload relays are PROTECTIVE DEVICES. After an overload relay has performed its safegarding function it must be reset by the EM before the system can again be run with overload protection. The several procedures for using them safely are presented in chapter 9 of this manual, in connection with CONTACTORS and other control devices.

REVERSE CURRENT AND PHASE-FAILURE DEVICES

An electrical distribution system can be overheated and damaged when two or more generators are employed, provided a condition exists which reverses the CURRENT in a d-c system, or reverses the POWER in an a-c system. Obviously, devices are needed to provide protection against these hazards.

To "plug" a motor is to stop the motor by setting the controls for reversing its direction of rotation. This practice is used with electric propulsion. Because propulsion type a-c motors

9151D1515

Figure 17-33.—PPI-scope, relative bearing presentation.

The fluxgate compass controls the position of the sweep on the indicators during true bearing operation. As the fluxgate compass follows the aircraft's changes in heading, the error signals coupled to the azimuth stabilization system change the position of the sweep. These changes in position occur at a one-to-one ratio. Thus, if the aircraft heading changes a certain number of degrees, the sweep secondaries will also change a like amount. Refer to figure 17-34 for a comparative analysis of true bearing operation.

In this operation the azimuth indicating device, as on relative operation, represents the heading of the aircraft provided the marker control on the radar control box is set to 0°. The action of moving the sweep secondaries to correspond with changes in the heading of the aircraft causes the azimuth indicating device to shift. Hence, the azimuth indicating device will always indicate the heading of the aircraft and, when on true bearing operation, the top of the scope always indicates north (provided the marker control on the radar control box is set to 0°). As the aircraft changes its heading, the targets remain in their position on the scope and only the azimuth indicator moves. Thus, the targets remain fixed, are always visible, and their relationship to the aircraft can be checked with the azimuth indicating device.

The top of the indicator represents magnetic north when the VARIATION is not set in, and true north when the variation has been set in. Variation is the angle between magnetic north and true north and differs at different points on the earth. The number of degrees of variation may be obtained from navigational charts.

1149 1120

require full voltage and current from all three phases supplied by the generator, phase-failure protection is a requirement where this type of shipboard propulsion is used.

REVERSE-CURRENT RELAY

Two or more d-c generators may be connected in parallel to supply sufficient power to a circuit. Each d-c generator is driven by its own prime mover. If one prime mover fails, its generator will slow down and draw power from the line. The generator will then operate as a motor and instead of furnishing power to the line, it will draw power from the line. This can result in damage to the prime mover and overloading of the generator. To guard against this possibility, reverse-current relays are used. The reverse-current relay connections are such that when the reverse power reaches a definite percentage of the rated power output, it will trip the generator circuit breaker, disconnecting the generator from the line.

Normally, the reverse-power settings for d-c relays are about 10 percent of rated generator capacity for d-c generators. The reverse-current relay (one for each generator) is located on the generator switchboard. The mechanical construction of a d-c relay designed to limit reverse-current flow is illustrated in figure 8-23.

77.103

Figure 8-23.—Mechanical construction of d-c reverse current relay.

11516

Note that the construction is similar to that of a bipolar motor with stationary pole pieces and a rotating armature.

The potential coil is wound on the armature, and a current coil is wound on the stationary pole pieces. When used as a protective device, the current coil is in series with the load, and the potential coil is connected across the line, as shown in figure 8-24. If the line voltage exceeds the value for which the potential coil is designed, a dropping resistor is connected at point X in the circuit.

When the line is energized, current flowing through the series coil produces a magnetic field across the air gap. Voltage applied to the armature winding produces a current in the armature coil, which interacts with the magnetic field, thereby developing a torque that tends to rotate the armature in a given direction. The construction of the relay is such that the armature cannot turn through 360 degrees as in a motor. Instead, the torque produced by the two fields plus the force from the calibrated spring tends to hold the tripping crank on the armature shaft against a fixed stop. This pressure is maintained as long as current flows through the line in the right direction.

However, if one generator fails, the voltage output of that generator will drop. When the voltage drops below the terminal voltage of the bus to which it is connected, the generator terminal current (through the relay series coil) will reverse. However, the polarity of the voltage applied to the potential coil remains the same. As soon as the reversed current exceeds the calibration setting of the relays, the armature rotates, and through a mechanical linkage, trips the circuit breaker that opens the bus. This action disconnects the generator from the line.

REVERSE-POWER RELAY

Reverse-power protection is required when two or more a-c generators are connected to the same line. Unless such protection is provided, failure of a prime mover can result in the generator running as a motor. An a-c reverse-power relay differs in construction from d-c reverse current relays. The a-c type consists of two induction disc type elements. The upper element is the timer, and the lower one is the direction element.

Figure 8-25 shows the coil and induction disc arrangement in the induction type relay timer element. The disc is four inches in diameter and is mounted on a vertical shaft. The shaft is mounted on bearings for minimum friction.

An arm is clamped to an insulated shaft, which is geared to the disc shaft. The moving

77.104

Figure 8-24.—D-c reverse current relay connections.

77.105

Figure 8-25.—Coil and disc arrangement, a-c reverse power relay.

81211517

contact, a small silver hemisphere, is fastened on the end of the arm. The electrical connection to the contact is made through the arm and a spiral spring. One end of the spring is fastened to the arm and the other end to a slotted spring adjuster disc fastened to a molded block mounted on the element frame. The stationary contact is attached to the free end of a leaf spring. The spring is fastened to the molded block, and a setscrew makes it possible to adjust the stationary contact position.

The main relay contacts (not shown in the figure) will safely handle 30 amperes at 250 volts d-c and will carry the current long enough to trip a breaker.

The induction disc is rotated by an electromagnet in the rear of the assembly. Movement of the disc is damped by a permanent magnet in front of the assembly.

The operating torque of the timer element is obtained from the electromagnets (fig 8-25). The main-pole coil is energized by the line voltage. This coil then acts as the primary of a transformer and induces a voltage in the secondary coil. Current then flows through the upper pole coils and thus produces a torque on the disc because of the reaction between the fluxes of the upper and lower poles.

The timer element cannot be energized unless the power flow is in the direction that will cause tripping. This interlocking action is accomplished by connecting the timer potential coil in series with the contacts of the directional element. Thus, the direction of power flow controls the timer relay.

The directional element is similar to the timing element, except that different quantities are used to produce rotation of the disc. There is also a different contact assembly. The two upper poles of the electromagnet are energized by a current that is proportional to the line current, and the lower pole is energized by a polarizing voltage. The fluxes produced by these two quantities cause rotation of the disc in a direction depending upon the phase angle between the current and voltage. If the line power reverses, the current through the relay current coils will reverse with respect to the polarizing voltage and provide a directional torque.

The contact assembly and permanent magnet construction are the same as that used for the timer element. The timer element is rated at 115 volts, 60 cycles. The minimum timer element trip voltage is 65 volts, and its continuous rating is 127 volts.

The directional element has a power characteristic such that, when the current and voltage are in phase, maximum torque is developed. The potential coil is rated at 70 volts, 60 cylcles.

The current coil rating is 5 amperes, and the minimum pickup current is 0.1 ampere through the coil. This current is in phase with 65 volts (minimum) across the potential coil. These are minimum trip values, and the timing characteristic of the timing relay may be erractic with low values.

For maximum protection and correct operation, the relay should be connected so that maximum torque occurs for unity power factor on the system. Because the directional element has power characteristics, this connection may be accomplished by using line to neutral voltage for the directional element potential coil (polarizing voltage) and the corresponding line current in the series coils. If a neutral is not available, a dummy neutral may be obtained by connecting two reactors, as shown in figure 8-26. When connected in this manner, the directional element voltage coil forms one leg of a wye connection, and the reactors from the other two legs of the wye. The voltage-operated timer element should be connected across the outside legs of the transformer secondaries.

PHASE-FAILURE RELAY

This type of relay is used to detect short circuits on alternating current propulsion systems for ships. Ordinary instantaneous trip relays cannot be used because, under certain conditions, for example when the motor is plugged (direction of rotation reversed on full voltage) during a crash stop, the momentary current may be as great as the short circuit current.

The relay in use operates when there is a current unbalance. It is connected in the control circuit so that it will shut down the system instantly in case of an external or internal fault. However, operation of the relay is not limited to short-circuit detection, and the relay may be used as a phase-failure relay. A phase-failure relay is shown in figure 8-27. Part A is the arrangement of the parts in the complete assembly, and part B is a closeup of the contact assembly. The entire unit is enclosed in a cover to prevent dirt and dust from interfering with its operation.

111518

Figure 8-26.—Schematic wiring diagram of an a-c reverse power relay. 77.106

0304411519

77.107

Figure 8-27.—Phase-failure relay.

The moving contact is the only moving element in the complete relay. There are two stationary contacts that make it possible to have the relay open or close a circuit when it operates.

Two coils are built into the relay. Each coil has two windings that are actuated by direct current from the two Rectox units. Four reactors are used to get sensitivity over a wide frequency range. Because variations in reactance are introduced during manufacture, two resistors are provided to balance the systems during the initial adjustment.

Figure 8-28 is the schematic wiring diagram for the phase-failure relay. The coils are represented by circles with numbers inside the circles that refer to numbered leads in the 3-phase bus. The coil (1-3) is connected to lines 1 and 3; the coil (1-2) is connected to lines 1 and 2; and the two coils (2-3) are connected to lines 2 and 3. However, the coils are not directly connected to the bus lines. Instead, connection is made through the Rectox units, which are connected to the line in series with a reactor.

When all three phase voltages are balanced, the flux produced by coil (1-2) is exactly equal and opposite to that produced by coil (2-3). The flux produced by coil (1-3) is exactly equal and opposite to that produced by the other (2-3) coil. Therefore, the resultant flux is zero, and no magnetic pull is exerted on the armature of the relay.

If a short circuit is placed across lines 1 and 2, no flux is produced by coil (1-2). This means that the flux produced by one of the (2-3) coils is no longer balanced, and there is a resultant flux, which exerts pull on the relay armature. The armature moves until the moving contact hits stationary contact 2 (fig. 8-27,B). This action opens the circuit between the moving contact and stationary contact 1. As soon as the short circuit is removed from lines 1 and 2, the resultant flux is zero, which allows the spring to return the armature to its original

77.108

Figure 8-28.—Schematic wiring of phase-failure relay.

11520

position. Similarly, if shorts occur on lines 2 and 3 or lines 1 and 3, the resultant flux is no longer zero, and the relay will operate.

A heavy copper tube is placed on each magnet core to damp out the triple-frequency ripple caused by the 120-degree displacement of the 3-phase voltages.

Figure 8-29 illustrates a wiring diagram of the relay, and figure 8-30 represents a vector diagram showing what happens to the line voltage when two lines are short-circuited. Suppose a short occurs across lines 1 and 2. The voltage on coil 1-2 will then be zero and the average voltage on coils 1-3 and 2-3 will be 100% sin 60°/1.11 = 78 percent of the normal rms value with no short. This voltage unbalance is enough to trip the relay.

The reactor in series with each coil keeps the coil current essentially constant over a frequency range of 12 to 90 cycles so that the relay sensitivity is as great at 12 cycles as at 90 cycles.

Mention was made of the use of resistors to achieve magnetic balance. If the reactor reactances are essentially equal, the resistors are

77.110

Figure 8-30.—Vector diagram showing perfect short circuit on 3-phase system.

77.109

Figure 8-29.—Wiring connections for phase-failure protection.

not needed. However, if manufacturing tolerances are such as to introduce unbalance, the resistors are necessary. To determine if the resistors are needed, connect a 3-phase, 115-volt, 60 cycle voltage to terminals 1, 2, and 3, as shown in figure 8-29. Short coils 1-3 and 2-3 (on a common core), and then remove the armature spring for that relay. Put the armature against the core. No pull should be exerted on it. If there is pull, a resistance is needed. Repeat this test for coils 2-3 and 1-3 with the coils 2-3 and 1-2 shorted.

Never open the d-c circuit to the Rectox rectifier while the voltage is being applied to the a-c side. This precaution is necessary because the voltage across the Rectox is only a small portion of the total voltage drop due to the reactor being in the circuit. If the d-c side is opened, full voltage is applied across the Rectox, which may cause it to break down.

Very little maintenance is required for this relay. No lubrication is needed. However, the relay should be kept clean so that dirt and dust will not interfere with its operation.

Because the relay rarely operates, it is advisable to check its operation every one or

11521

two months. To do this, short circuit the coil connections one at a time. Do this with a tool that has an insulated handle to avoid electric shock. When the coil is shorted, the armature will drop because the coil is no longer energized. When the short is removed, the armature will return to its normal position.

SAFETY PRECAUTIONS

Electrical safety is an all hands job. However, every Electrician's Mate must understand that every electrical device which he handles carelessly can cause death to himself or to others. The EM must never let familiarity with his work lessen the habitual determination to be careful and, by that means, to stay alive.

If the EM does not know the safe way to do his work, it will pay him to find out. This requires using PRECAUTION constantly—taking measures BEFOREHAND to ward off accident, or to secure success without harm to himself or others. Some specific precautions, which apply while handling protective devices, are presented herewith for the three-phase distribution system of figure 8-3.

Figure 8-3 illustrates that all fuses are "hot" when power is being furnished by the main supply. Therefore, use extreme care while working at fuse locations. Always remove and replace fuses with an approved fuse puller. This tool is insulated so that there is less danger from electric shock to the electrician while he is working with fuses.

Fuses of a rating greater than 10 amperes should be removed and replaced only after the circuit has been deenergized. This action prevents drawing an arc when the fuse is removed.

Branch circuits are made safe to work on by opening the switch associated with that circuit. These switches should be tagged, "WARNING SHOCK HAZARD This circuit was opened for repairs and shall not be closed except by direct order of _____." If more than one repair party is engaged in repair work on an electrical circuit, a tag for each party should be placed on the supply switch.

After work has been completed, each party should remove its own tag, but no other.

11522

77.111

Figure 9-1.—Pushbutton symbols.

bar and button, for the purpose of opening the electrical circuit after the manual pressure is released.

Another arrangement for getting spring action is to use a strip of springy metal that is firmly mounted only at one end, leaving its other end free to move when its free end is pushed by the insulated button. This arrangement may be modified in practice where a pushbutton control may take one of many forms. A very common practice is to affix one contact to the springy bar, while the remaining terminal of the pair remains fixed. The one symbol shown at the top of figure 9-1, of course, serves all variations that may be found in actual practice for a very simple switch to turn current ON momentarily, then OFF when physical pressure is released from the pushbutton.

Pushbutton controls are shown on equipment schematics, and figure 9-1 illustrates and describes the symbols used to indicate the buttons and the contact arrangement at each button.

Pushbutton control is suitable for momentary application or interruption of current. When a pushbutton is used to apply current for a considerable time, a latching device is incorporated to hold operation (maintain contact) until the latch is released.

KNIFE SWITCHES

Knife switches no longer are used for modern ship applications but their representative symbols (fig. 9-2) are basic standards for other similar switches.

In its simplest form, a knife switch has a movable conductive arm (usually copper), which is hinged or pivoted to a fixed support that forms one terminal of the switch. The second switch terminal is fixed in position so that it may be engaged by the moving arm. Usually, this contact is made of copper and is arranged so that it contacts both sides of the switch arm when the switch is closed. The second terminal has a natural spring to provide a tight contact that is self-wiping. That is, each time the switch is opened or closed, the moving arm will be rubbed by the fixed contact, keeping the contact surfaces clean and bright.

Another type of knife switch may have the arms and contacts arranged to perform a number of actions. This type, with one moving arm and one closed position, is a single-pole, single-throw (SPST) switch, and may be used to open or close one conductor only. In many cases, it

77.112

Figure 9-2.—Schematic switch symbols.

11524

is necessary to open or close two conductors simultaneously. Switches for this purpose are double-pole, single-throw (DPST) and have two moving arms connected by an insulating bar. This type has two hinged and two fixed contacts.

The number of arms on a switch is determined by the number of conductors it controls. Thus, we may have three-pole, single-throw (3PST) or four pole, single-throw (4PST) switches. In each case, the moving arms will be connected by an insulated bar, for simultaneous operation.

A knife switch may be mounted on a base of bakelite, hard rubber, or slate in order to insulate the conducting parts of the switch from other surfaces. However, open switches can be extremely dangerous because the conductors are exposed. Therefore, most switches are enclosed in a metal cabinet. The switch arm or arms are then operated by an external lever, which is mechanically coupled to the insulating bar on the switch arms.

Knife switches may be used to supply power to two different circuits (loads). When they are used in this manner, the moving arms are arranged so that when they are thrown in one direction one set of contacts is engaged and when the arms are thrown in the other direction, a second set of contacts is engaged. These switches may have any number of poles and are identified as single-pole, double-throw (SPDT); double-pole, double-throw (DPDT); triple-pole, double-throw (3PDT); or four-pole, double-throw (4PDT). The schematic symbols for each designation are illustrated in Figure 9-2.

ROTARY SWITCHES

One type of switch used to open or close one or more conductors is the rotary type. This type is constructed so that the moving arm or arms are pivoted in the center. These arms are insulated from each other and from the pivot post. The contact arrangement is such that a moving arm is connected to two fixed contacts at the same time. Because the circuit wires are connected to the fixed contacts, the arm closes the circuit.

It is possible to construct a rotary switch in a very compact form. However, the amount of current and voltage to be handled by the switch determines the size of the switch arms and contacts as well as the spacing between them. The advantage of a rotary switch is that the number of positions and the number of poles can be increased by arranging the fixed contacts on wafers.

Because there are 360° in a circle, it is possible to have 35 contacts and an OFF position, each position spaced 10° apart. For applications requiring low voltage and current, one set of contacts can be placed on one side of the wafer and another set of contacts placed on the opposite side of the same wafer. Because wafers may be separated as little as 3/8 of an inch in some applications, it is possible to have an 8-pole, 36-position switch in a space approximately 2 inches in diameter and 1 1/2 inches deep. This kind of rotary switch is used in many electronic applications. However, one type of rotary switch is rated at 500 volts a-c at 200 amperes and may be used on power applications.

MASTER SWITCHES

The switches encountered in naval equipment will fall into the three general types that have been described. However, special applications change the previously described simplified forms. A master switch (pushbutton, knife, or rotary) starts or stops a sequence of operations. A device that is controlled by a master switch cannot be used until the switch is closed. The actual closing of the switch may be done manually or automatically. In some circuits, the master switch may be followed in sequence by other controls that are designed for a specific purpose. These will be described later.

Master switches are used with the faceplate and cam-type controllers. The principal difference is in the method of making contact between the fixed and moving terminals. A schematic diagram of face-plate internal connections is given in the d-c motor starter circuit of figure 9-3.

In the face-plate switch, connection is made from one side of the line to a handle-operated lever that carries a contact brush or shoe. Pushing the handle (fig. 9-3) moves the brush over a series of contacts (fixed), which are connected to resistors. As the lever arm moves clockwise across the contacts, the amount of resistance in series with the armature gradually decreases. At the last contact, all series resistance is out of the circuit, and the armature receives full voltage.

When the lever closes the circuit at the first contact, it establishes a circuit to an electromagnet. The current flowing through the magnet

11525

Figure 17-34. —PPI-scope true bearing presentation.

Some compass systems provide a means whereby variation may be added into the system; thus the compass will then indicate true north, and a radar slaved to the compass will also indicate true north. In some aircraft installations that are equipped with a compass that does not provide this correction feature, a variation differential generator is included. This generator is between the transmitting synchro of the compass and the azimuth followup synchro in the radar. By adjusting this generator to the local variation, it is possible to correct the radar to true north.

True Bearing Amplifier

The input to the true bearing (servo) amplifier (fig. 17-35) is obtained from the rotor of the azimuth followup synchro. This error signal is applied across resistor R1 (sensitivity adjustment) which is paralleled by the primary of input transformer T1. The amplitude of this signal is determined by the amount of change in the aircraft heading, and the phase is determined by the direction of the change. The signal is transformer coupled to the grids of V1 which is the true bearing amplifier discriminator. The signals on the grids of V1, due to the transformer action, will always be 180° out of phase. The plate voltages, due to the transformer connections, are always in phase. Thus, the grid that is in phase with the plate will determine which half of the duotriode conducts the hardest.

When the grid and plate of V1 (A) are in phase, its conduction charges the capacitors in the plate circuit. The plate current circuit is from the plate of V1 (A) through the

CAIT 1150

77.113

Figure 9-3.—D-c motor starter circuit.

winding produces a magnetic flux, which holds the lever at the last contact.

Face-plate switches are used on older ships as starting switches in d-c motor circuits. They will seldom be found on ships that have a-c electrical systems. In the three-terminal type (fig. 9-3) the current through the holding magnet winding is actually the shunt field current of the motor being controlled. Therefore, if the voltage supply for the motor field is interrupted for any reason, the reduction in field current will reduce the strength of the holding magnet, and the lever will be released. Because the lever is spring loaded, it will return to the OFF position. This feature makes it impossible to open a motor field circuit at some point and then close the circuit (with the motor connected to the line). As soon as the holding coil magnet releases the lever, it returns to the OFF position, and the motor cannot be started without going through the entire starting procedure.

Cam-type switches (fig. 9-4) are suitable for use with multispeed, reversing, and nonreversing controllers.

Cam-type switches are manually operated by turning a handwheel or lever located on one side of the switch housing. Turning the handwheel rotates the shaft on which the operating cams are mounted. These cams engage rollers mounted on the switch contact levers and cause the switch contacts to open or close.

Some cam switches are self-centering. That is, it is necessary for the operator to hold the operating control at the desired position. When the control is released, it returns to the OFF position. In the nonself-centering type, the operating control remains in the position selected until the operator turns it to another position. A star wheel mechanism provides positive positioning on the nonself-centering type of master switch given in figure 9-4A. Parts A and B show how rotation of the cam causes the switch contacts to open and close, and part C illustrates how the star wheel latches the switch in position.

The operating cams are made of phenolic material and are mounted on a hexagonal steel shaft. The operating sequence of the switch contacts is determined by the shape of the cams and their orientation on the shaft. Cam-type master switches may be mounted on a bulkhead, deck, or pedestal. Regardless of the type of mounting or the number of poles or positions, the method of operation is the same.

MAGNETIC SWITCHES

Magnetic switches are switching devices actuated by means of an electromagnet, controlled either manually or automatically, which perform functions for making, breaking, or changing the connections of an electric circuit. Since relays and contactors fall under this general definition, those magnetic switches are presented later in this chapter.

LIMIT SWITCHES

In certain applications the ON-OFF switch does not give enough control to ensure safety of equipment or personnel. A limit switch is incorporated in the circuit in order that operating limits are not exceeded.

The limit switch is installed in series with the master switch and the voltage supply. Any action causing the limit switch to operate will open the supply circuit.

One application of limit switches is in equipment that moves over a track. It is possible to apply power so that operation will continue until the carriage hits an obstruction or runs off the end of the track.

If limit switches are installed near the end of travel, an arm or projection placed on the moving section will trip a lever (as shown in figure 9-5) on the limit switch. The switch then opens the circuit and stops the travel of the carriage. This type of control is a direct-acting, lever-controlled limit switch. Another type, an intermittent gear drive limit switch, may be coupled to a motor shaft to stop action

Figure 9-5.—Limit switch, roller actuator arm operated.

when a definite number of shaft revolutions is completed.

FLOAT SWITCHES

A float switch (figs. 9-6 and 9-7) controls electrically driven pumps used to fill or empty tanks.

Construction

In a tank installation (fig. 9-6) the deck and overhead flanges are welded to the deck and overhead of the tank. The float guide rod, E, fits into the bottom flange and extends through the top flange. The float guide rod then passes through an opening in the switch operating arm. Collars A and E on the guide rod exert upward or downward pressure on the operating arm as the float approaches minimum or maximum depth positions. The switch operating arm is fastened to the shaft, which is coupled to the switch contact mechanism (fig. 9-7). Collars C and D on the guide rod are held in position by set-screws so that their positions can be changed to set the operating levels to the desired points.

As the float goes up and down, corresponding to the liquid level, it does not move the operating rod, E, until contact is made with either collar. When the float comes in contact with either collar, the external operating arm of the switch is moved and the switch is operated.

Although the switch assembly is of rugged construction, it must be checked regularly for proper performance.

Maintenance

The switch contacts should be kept in good electrical condition. Determine the kind of metal used for the contacts, whether copper or silver, and apply applicable procedures outlined in chapter 8 for maintenance of the kind of contact metal in use. Of course, contacts should never be cleaned while power is applied to the circuit.

Lubricants should not be applied to contact surfaces.

PRESSURE AND TEMPERATURE SWITCHES

Pressure and temperature controls have been grouped together because the switching mechanism is the same for both controls; the difference is in the operation.

Pressure-controlled switches are operated by changes in pressure in an enclosure such as a tank. Temperature-controlled switches operate from changes in temperature that take place in an enclosure or the air surrounding the temperature-sensing element. Actually, both switches are operated by changes in pressure. The temperature element is arranged so that changes in temperature cause a change in the internal pressure of a sealed gas or air-filled bulb or helix, which is connected to the actuating device by a small tube or pipe. Temperature changes cause a change in the volume of the sealed-in gas, which causes movement of a diaphragm. The movement is transmitted by means of a plunger to the switch arm. The moving contact is on the arm, and a fixed contact may be arranged so that the switch will open or close on a temperature rise.

When the switch is used to control pressure, the temperature element is replaced by a tube that leads to the pressure tank. The pressure inside the tank then operates the switch mechanism.

11528

77.116

Figure 9-6.—Float switch tank installation.

Pressure or temperature controls may be used as a pilot device (fig. 9-8). The circuit operation is exactly the same regardless of the kind of pilot device used to control the circuit. To maintain more or less constant temperature or pressure, switch contacts are arranged to close when the pressure or temperature drops to a predetermined value and to open when the

0C3IL11529

pressure or temperature rises to the desired value. The reverse action can be obtained by changing the contact positions.

The difference in pressure for contact opening and closing is the differential. The switch mechanism has a built-in differential adjustment so that the differential can be varied over a small range. Once set, the differential remains essentially constant at all pressure settings.

Each switch has a range adjustment that sets the point at which the circuit is closed. Changing the range adjustment raises or lowers both the closing and opening points without changing the differential.

77.117

Figure 9-7.—Float switch mechanism.

Operating Adjustments

To set the operating range of the switch, turn the differential adjustment screw (fig. 9-9) counterclockwise against the stop for minimum differential. Bring the pressure to the value at which the circuit is to be closed. If the switch contacts are open at this pressure, turn the range screw slowly clockwise until the contacts close. If the contacts are closed when the desired pressure is reached, turn the range screw counterclockwise until the contacts open; then turn the screw slowly clockwise until the contacts close. These adjustments set the closing pressure.

The pressure (keep in mind that changes in temperature are converted to changes in pressure) is now raised to the point where the circuit is to be opened. When this point is reached, turn the differential screw slowly clockwise until the contacts open, this adjustment sets the opening pressure.

Thermal Unit Type

The bulb and helix units can be connected to the switch section (fig. 9-10). The bulb unit (fig. 9-10A) is normally used when liquid temperatures are to be controlled. However, it

77.118

Figure 9-8.—Typical pilot device control circuit.

11530

77.119

Figure 9-9.—Pressure-operated switch.

77.120

Figure 9-10.—Thermal units.

may control air or gas temperatures, provided the circulation around it is rapid and the temperature changes at a slow rate.

The helical unit (fig. 9-10B) has been specifically designed for air and gas temperature control circuits. To be most effective, the thermal unit must be located at a point of unrestricted circulation so it can "feel" the average temperature of the substance that is to be controlled.

Some switches are stamped, "WIDE DIFFERENTIAL." They are adjusted in the same manner described for the regular controls. However, because of slight design changes it is possible to get wider variation in differential settings.

Maintenance

When adjusting temperature controls, allow several minutes for the thermal unit to reach the temperature of the surrounding air, gas, or liquid before setting the operating adjustments. After adjusting the operating range of pressure or temperature controls, check the operation through at least one complete cycle. If you find variation from the desired operating values, go through the entire procedure again and observe operation through a complete cycle.

PILOT CONTROL DEVICE

A pilot is defined as a director or guide of another thing (or person). You may be familiar with ship pilots, pilot rudders, and pilot flames. In this text, a pilot is a small device that controls a relatively larger device or mechanism, usually doing so by electrical means. The previously described float switch and pressure operated switches are representative examples of such pilot devices. Pilot devices are limited in their ability to handle large currents and voltage required to operate shipboard motors or power-handling units. Therefore, it is customary for a pilot device to actuate only a magnetic switch. The magnetic switch can be chosen with characteristics suitable for handling the desired amount of power in the motor circuit.

Use of a Pilot Device

Float switches used as pilot devices control the pump operation through other controls. A typical control circuit is shown in figure 9-8.

Switch S1 makes it possible to have either manual or automatic operation of the motor-driven device. When this switch is in the manual

11531

position (the circuit is closed by the start-stop switch, S2) current flows through the contactor (holding coil M1) which pulls line contacts M closed and applies power to the motor. The motor will then operate until it is stopped manually.

With S1 in the automatic position, and the start-stop switch closed, the motor will not run unless the switch on the pilot device is closed. When the pilot device (in this example, the float switch) closes the circuit, current flows through the arm of S1 to the operating coil, M1, which then pulls the line switch contacts closed and starts the motor. The motor drives a pump that fills the tank. When the liquid in the tank rises to the desired level, the pilot device opens the circuit and removes voltage from the operating coil. This action allows the line contacts to open and stop the motor. This start-stop action will continue automatically as long as the start-stop switch is in the ON or START position and S1 is in the automatic position.

RELAYS AND CONTACTORS

The RELAY and CONTACTOR are small and large versions, respectively, of a magnetically operated device. Some Navy contactors can switch 10,000 amperes.

The basic difference in these devices designed for use on alternating current and those designed for direct current is in the armature and magnet core construction.

D-C RELAYS AND CONTACTORS

The d-c relays described in chapter 8 are primarily used with pilot devices to operate the larger contactors or circuit breakers.

The complete contactor is composed of an operating magnet, which is activated by either switches or relays, fixed contacts, and moving contacts. It may be used to handle the load of an entire bus, or a single circuit or device. However, when heavy currents are to be interrupted, larger contacts must be used. The contacts must snap open or closed to reduce contact arcing and burning. In addition to these precautions, other arc-quenching means are used.

Magnetic Blowout

When a d-c circuit carrying appreciable current is interrupted, the collapse of the flux linking the circuit may induce a voltage, which will cause an arc. If the spacing between the opened contacts is small, the arc will continue once it is started. The arc, if it continues long enough, will either melt the contacts or weld them together. To correct this condition, make the open contact spacing great enough to extinguish the arc. This may be impracticable because of space limitations and the fact that long stroke operating magnets require heavy current for operation.

Magnetic "blowouts" were developed to overcome these objections. These devices provide a magnetic field, which blows out the arc in much the same manner as you would blow out a match. Figure 9-11 illustrates how a magnetic field is set up for arc blowout. The conductor is represented by the shaded circle (fig. 9-11A), and electron flow in the conductor is assumed to be flowing away from you as you look at the drawing. The direction of the magnetic flux around the wire is then counterclockwise, as shown by the circled arrows, and the blowout flux is established from left to right, as shown by the horizontal straight arrows.

The flux around the conductor and the blowout flux oppose each other above the conductor and combine into a strong field below the conductor. This action produces a force on the conductor in an upward direction, as shown by the vertical vector (fig. 9-11B). If the conductor (fig. 9-11A) is formed by contacts and the contacts are opened, the air between them becomes a conductor while the contacts are arcing. The resultant magnetic field created by the arc and the blowout field forces the conducting air upward. This lengthens the conductive path (fig. 9-11B) and extinguishes

77.121

Figure 9-11.—A magnetic field is set up for arc blowout.

11522

the arc. The effective arc gap is several times as large as the gap measured straight across from one contact to the other.

The magnetic blowout operation is illustrated in figure 9-12. It is important that the fluxes remain in the proper relationship. Otherwise, if the direction of the current is changed, the blowout flux will be reversed and the arc will actually be pulled into the space between the contacts.

When the direction of electron flow and flux are as illustrated in figure 9-12, the blowout force is upward. The blowout effect varies with the magnitude of the current and with the blowout flux. The blowout coil should be chosen to match the current so that the correct amount of flux will be obtained. The blowout flux across the arc gap is concentrated by a magnetic path provided by the steel core in the blowout coil and the steel pole pieces extending from the core to either side of the gap.

Arcing Contacts

Because arcing at contacts wears away the usable surface, a second set of contacts (arcing contacts) is shunted across the main contacts.

A shunt-type contactor that will handle 600 amperes at 230 volts is pictured in figure 9-13. The blowout shield is removed in the pictorial view (fig. 9-13A). The diagram (fig. 9-13B) shows the main sections of the contactor. The arcing contacts ⑦ are made of rolled copper, which has a heavy protective coating of cadmium. These contacts are self-cleaning because of a sliding or wiping action after the initial contact is made. The wiping action keeps the surface bright and clean and thus maintains a low contact resistance.

The contactor is operated by connecting the coil ① directly across a source of direct voltage. When the coil is energized, the movable armature ② is pulled toward the stationary

magnet core ③. This action causes the contacts that carry current ④, ⑤, ⑥, and ⑦ to close with a sliding action.

The main contacts, ④ and ⑤, are called brush contacts. They are made of thin leaves of copper, which are backed by several layers of phosphor bronze spring metal. A silver brush arcing tip ⑥ is attached to the copper leaves and makes contact slightly before the leaf contact closes. The stationary contact consists of a brass plate ⑯, which has a silver-plated surface. The plating lowers the surface resistance, and therefore the contact surfaces should never be filed or oiled. If excessive current has caused high spots on the contact, the high places may be smoothed down by careful use of a fine ignition-type file.

A detailed side view of the contacts is given in figure 9-14. Operation and contact spacing may be checked by manually closing the contactor (be sure the power is off). The lowest leaf of brush contact ⑤ in figure 9-13B, should just barely touch plate ④. If the lower leaf hits the plate too soon, the entire brush assembly should be bent upward slightly.

The contact dimension, A (fig. 9-14), should be measured with the contactor in the OPEN position. The distance should be 1 1/2 inches and is adjusted by moving stop ⑫ in figure 9-13B up or down.

The arcing tip dimension, B, should be 1 1/4 inches and is adjusted by bending the arcing tip at point C. The arcing contact dimension, D, should be 1 1/4 inches and is set by the addition of spacer washers or shims at point E.

Tail spring ⑩ in figure 9-13 should be set by means of the adjustment nut ⑪ so that with the contactor inclined 45° backward, the armature ② will return to its open position when closed and then quickly released. This adjustment gives the tail spring the minimum tension required. If the contactor cannot be

11534

77.124

Figure 9-14.—Detailed view of contacts.

tilted 45° backward, the tail spring should be adjusted so that the contactor will pick up at 70 percent of the line voltage.

Main Contacts

The main contacts, ④ and ⑤, in figure 9-13 carry the d-c current drawn by the load during the operating cycle. The contact dimensions vary in accordance with the current handled by them. However, in most cases the same principles are used and the only difference is in physical size.

The moving main brush contact ⑤ is hinged to the armature. A rod fastened to the armature extends through the slot in the moving contact arm. A finger spring ⑬ is held under compression between the washer at the end of the rod and the moving contact arm. With the armature open, the spring holds the moving contact arm against the armature, which drops back and opens the contacts. When the armature is attracted, the contacts touch before the armature is pulled against the pole piece. The continued pull of the magnet compresses the spring so that it adds to the pressure, holding the moving contact against the fixed contact.

Electric Interlock

The voltages present in most electrical enclosures are dangerous. An electrically operated interlock is sometimes used to safeguard personnel and prevent opening of the d-c or a-c enclosure while it is energized.

A pictorial view and a diagram of an electric interlock are shown in figure 9-15, A and B respectively.

The components of this electric lock are identified in part B. The coil of the lock is connected to the line terminals. As soon as the power is turned on, voltage is applied to the lock coil (1), the armature (2) is pulled toward the magnet core (3), and the latch (4) engages the door hook (5) in the enclosure door. The door of the enclosure cannot be opened as long as the coil is energized.

When the contactor is deenergized, the lock magnet releases the armature, which disengages the latch from the door hook.

Mechanical Interlock

When contactors are designed for two-speed or forward and reverse operation, it is possible to actuate the FAST or forward control at the same time the SLOW or reverse control is in operation unless precautions are taken. Simultaneous operation of the two controls is prevented by the use of a mechanical interlock arranged so that as one contactor closes, the other contactor is mechanically locked open.

Shunt D-C Contactors

Contactors for motor control are designed to energize or deenergize a circuit repeatedly without failure. Figure 9-16 is a d-c shunt contactor. Part A is the external view, and part B illustrates the mechanical construction.

The contactor is operated by energizing coil ①, which is composed of a large number of turns of wire and connected directly across a source of voltage. Armature ② is pulled against core ③, which closes the main contacts, ④ and ⑤. The contacts are shaped to give a sliding motion when they close. Shunt-type d-c contactors are generally used as main-line or accelerating contactors. However, they are not restricted to this usage and can be used for many other power-control applications.

11535

Figure 17-35. —True bearing amplifier.

source potential winding, plus to minus, then up through resistor R5. The current flowing through R5 develops a negative voltage at the bottom and charges capacitor C6. C6 in conjunction with C5 provides an a-c filter path to ground. The current flows from the junction point to resistors R4 and R5 back to the center tap of transformer T1. The path is then completed back to the cathode through the resistor R2 and the balance pot R3. During this same time, although V1 (B) has its grid negative and plate positive, it may still conduct a little. Its conduction path from the plate through the source potential causes current to flow through resistor R4 and develop a negative voltage at the top of R4. The negative voltage developed at the bottom of R5, however, far exceeds the negative voltage developed at the top of R4. Thus the voltage measurement from R5 is negative to positive. The voltage thus developed is coupled to the grids of the output control tubes.

The grid of V2 (B) is more negative than the grid of V2 (A). Any portion of the a-c signal not filtered out through capacitors C4, C5, and C6 is coupled through C7 and C8 to the grids of V2. In addition, the d-c signal developed across R6, R7, R8, and R9 is taken from the junction of the resistors and also applied to the grids. Hence, the grids contain both a-c and d-c components.

When the amplitude of the signal on either grid is too great, grid current is drawn; this limits the conduction of the tube. For example, when the amplitude of the signal on the grid of V2 (A) is excessively positive, grid current will flow through R10 and R12, thus adding to the bias on V2 (A).

The cathode of V2 is tied directly to ground. The voltages applied to the plates of V2 are in phase and conduction depends upon the grid signals that are developed in the discriminator circuit. In the case cited previously where V1 (A) conducted the hardest, the voltages developed in the output resistors made the grid of V2 (B) most negative. Under these conditions, the current flowing through the plate windings of the bottom control winding of the SATURABLE REACTOR assembly, T2, will be less than the current flowing through the upper

Series Lockout D-C Contactors

A delay in circuit closing is desirable in some motor-control applications. The contactor used for this purpose is called a lockout type because the delay action is obtained by using a lockout coil. This coil gets its name from the fact that it locks the main contacts open on initial surges of heavy currents and then allows the contactor to close after the current has fallen to a predetermined value. A lockout-type contactor is used as an accelerating contactor on current-limit acceleration controllers.

Single-Coil Lockout

As may be seen from figure 9-17 the upper part of the contactor is very similar to other magnetic contactors. However, the lower part incorporates the lockout mechanism, which consists of an armature ② (an integral part of the closing armature ③), a lockout coil ①, and a means of adjusting the air gap so as to obtain the desired operation with respect to motor current. The contactor has two magnetic circuits with the magnetic paths shown by the dashed lines in figure 9-17B. The upper part of the control consists of the closing coil ④, the closing armature ③, and the contacts.

In operation, both coils are energized at the same time. The closing coil ④ may be connected across the line (shunt or in series) with the motor which is being controlled. The lockout coil ① is connected either across part of the motor circuit or in series with the motor circuit.

The high starting current surge causes a strong magnetic field in the lockout. This strong field overcomes the field about the closing coil ④ and holds the contactor in its open position. As the motor accelerates, the heavy starting current decreases, and, at a predetermined current value, releases the lockout armature ② and allows the contacts to close. The adjustment of the magnetic air gap, B, determines the current at which the lockout coil releases the armature.

This current is set by the screw disc ⑥. Turning the disc clockwise decreases the magnetic air gap, B, which means that fewer ampere turns will be needed to lock open the contactor. Thus, a longer interval is required to allow the current to reduce to the lower release point. The motor will then accelerate more slowly.

Double-Coil Lockout

Although the contactor just described has two coils (lockout and holding), it is known as

a single-coil lockout contactor. The type that will now be described is a double-coil lockout contactor (fig. 9-18).

As shown in the figure, the double-coil unit has a series up-coil and a series down-coil in addition to a shunt coil. The series up-coil ① and the series down-coil ② are connected in series with each other and the motor armature. The series down-coil serves to hold the contactor armature ④ in the open position during the motor starting high-current surge. When the current drops to the predetermined value, the combined magnetic pull of the up-coil and the shunt coil is greater than the magnetic pull of the down-coil, and the armature ④ closes the main contacts, ⑤ and ⑥. The shunt coil ③ is used to hold the contactor closed when the load on the motor is light. Because it is designed for connection across the line, it has many turns of fine wire. The contacts of this relay have the same shape and construction as those used on contactors previously described.

Coils

The coils used in contactors operate as electromagnets. The basic theory of electromagnet operation is given in Basic Electricity, NavPers 10086 (revised). Study or review this material so that you will be familiar with the operating principles.

Dashpot

One type of d-c overload relay is called a dashpot relay because of its construction (fig. 9-19). Part A is a photograph of a dashpot relay and part B is a diagram showing the various parts.

77.127

Figure 9-17.—D-c lockout contactor.

The contacts ② are normally closed, and any circuit in which the relay is connected will be closed. The relay coil ① is normally connected in series with the line to be protected so that changes in the line current will influence the magnetic flux of the coil.

Dashpot assembly ⑦ is filled with oil, and the dash ⑬ is a disc that has a slightly smaller diameter than the inside diameter of the pot. The dash is connected to a plunger assembly ③, which is a part of the solenoid assembly. The contacts ② are mounted on this plunger.

When the current in relay coil ① exceeds the normal rated current, the magnetic force on plunger ③ pulls it slowly upward. The upward motion is slowed down because of the opposition offered the metal disc by the oil in the dashpot.

The overload current keeps exerting a pull on the plunger until the rising plunger opens the normally closed contacts, which open the control circuit. When the circuit is opened, current no longer flows through the coil and there is no pull on the plunger. The relay then resets itself as the plunger and contacts return to their normal positions.

The use of oil in the dashpot (1) acts as a time delay medium because it slows the movement of the disc; (2) because the contacts are immersed in the oil, serves as an arc-quenching or cooling medium; and (3) acts as a shock absorber because it slows the motion of dash ⑬ and contacts ② under shock impacts.

The relay is set, at the factory, to trip when the line current is slightly above the current rating of the motor it protects. This, together with the time delay feature, prevents tripping of the overload under normal starting current surges.

A-C RELAYS AND CONTACTORS

Basically, the construction, operation, and application of either an a-c contactor or an a-c relay is the same as its d-c counterpart. However, because of the characteristics of alternating current, the differences in construction must be recognized.

A-C Magnets

The cores used for a-c magnets are of laminated construction so that eddy currents may be reduced.

Shading Coils

Because the flux in a single-phase magnet is in phase with the coil current, the magnetic pull at the air gap varies with the frequency of the supply voltage. Therefore, twice each cycle, the pull will go to zero, andthe armature will chatter against the core. The noise is objectionable, and the chattering causes excessive wear on the magnet core face. The noise and wear is overcome by a shading coil imbedded in one of the magnet faces (fig. 9-20).

The shading coil acts as the secondary of a transformer. The effect of the shading coil is to cause the main coil flux to be out of phase with the shading coil flux so that when the main coil flux goes through zero, the shading coil flux will be high enough to maintain pull on the armature and keep it closed.

Most d-c magnets and some a-c types have a second air gap, shown above the hinge in figure 9-20. This gap must not be closed when the armature is pulled in because its purpose is to prevent residual magnetism from holding the armature closed after the coil has been deenergized.

The design of an a-c magnet is more complicated than that for a d-c magnet. Long stroke magnets are likely to have a pull, which, at first, increases as the gap decreases, and then stays fairly constant until the gap becomes nearly closed. The pull then increases sharply as the gap decreases to zero. Figure 9-21 illustrates how the pull increases as the gap becomes smaller. Note that as the pull becomes greater, the coil current and wattage decrease.

The current decreases because the reluctance of the magnetic circuit decreases as the air gap becomes smaller; hence, the flux

density and reactance increase, the principal opposition to the coil current is the inductive reactance of the coil. With a rising inductive reactance and a constant potential source, the current will decrease.

Shunt A-C Contactors

Shunt type a-c contactors have laminated frame construction, and the coils are wound with many turns of fine wire. The coils are designed for connection directly across the line and are rated for either continuous or intermittent operation. Usually, shunt-type a-c contactors are used to control motor circuits. The initial control impulses may come from a pilot device or from a manual control, which serves as a master switch for the contactor.

Magnetically operated starters for a-c motors may be connected to give under-voltage protection, as shown in figure 9-22.

The circuit used for under-voltage protection with manual restart employs momentary contact pushbuttons (fig. 9-22). The motor is started by pushing the START button. This action completes the circuit from L3 through the control fuse, STOP button, START button, the overload relay contacts, OL, and the contactor coil, M, to L1. When the M coil is energized, it closes line contacts M1, M2, and M3 which connect the full line voltage to the

254 11540

77.131

77.132

Figure 9-22.—Under-voltage protection.

motor. The line contactor auxiliary contact, MA, also closes and completes a holding circuit for energizing the coil circuit after the START pushbutton has been released.

The motor will continue to run until the contactor coil is deenergized by the STOP pushbutton, failure of the line voltage, or tripping of the overload relay, OL.

Under-voltage protection with manual restart is provided by the use of momentary contact pushbuttons. If coil M is deenergized, the contactor will not reclose and start the motor when voltage is restored, or when the overload relays are reset until the START pushbutton is again depressed. The overload relays, OL, are reset by a reset button on the outside of the motor starter cabinet. An under-voltage release circuit with automatic restart employs a maintained contact, STOP-START, switch (fig. 9-23). The motor is started by turning the switch to the START position. This action completes a path from L3 through the fuse and maintained contact of the STOP-START switch to the overload relay contacts, OL, and the contactor coil, M, to L1. When the contactor coil, M, is energized, it closes line contacts M1, M2, and M3, which applies full line voltage to the motor. The motor will continue to run until the coil, M, is deenergized by loss of voltage, tripping of the overload relay, or by turning of the STOP-START switch to the STOP position. Under-voltage release with automatic restart is provided by the use of maintained contacts on the STOP-START master switch. If the operating coil, M, becomes deenergized through loss of voltage, the contactor will close and restart the motor as soon as voltage is restored or when the reset button for the overload relay is pressed if an overload caused the M coil to be deenergized. These forms of operation are necessary to protect motors from overheating due to under-voltage conditions.

RHEOSTATS

It is often necessary to reduce the voltage that is being applied to a motor, a generator field, a lighting circuit, or some other electrical device.

One method of reducing voltage is to introduce resistance in series with the load. The amount of resistance in the circuit may be a

77.133

Figure 9-23.—Under-voltage release.

1541

fixed value, or it may be varied mechanically. Where mechanical variation of resistance is provided and the unit is connected in series with a load, it is called a rheostat.

MANUAL

Rheostats are classified as continuously variable or step types. In the continuous type, a moving arm makes contact with a resistance wire. One end of the wire is connected to one circuit lead, and the moving arm is connected to the other circuit lead. Thus, movement of the arm over the resistance wire varies the effective circuit resistance from zero up to the full resistance of the resistance element.

In the step type, fixed resistors are connected in series, and the junctions between adjacent resistors are connected to contacts arranged either in a straight line or a circular form. When the contacts are arranged in a straight line, the moving contact is driven by a worm gear. When the contacts are arranged in circular form, the moving contact is pivoted in the center of the circle.

Because considerable current may be present in some applications, the moving contact is arranged to make contact with one fixed contact before breaking the connection to another fixed contact. This prevents arcing and momentary interruptions of current.

When a rheostat is used to lower voltage, the difference between the source voltage and the load voltage will appear across the rheostat terminals. This voltage is sometimes called a voltage drop and is equal to the resistance in OHMS times the current in amperes flowing through the resistance. The voltage-dropping action is illustrated in figure 9-24. The rheostat (fig. 9-24A) is set for zero resistance; all resistance is cut out by the moving arm. Under this condition, there is no current flowing through the resistance and no voltage drop across the rheostat. Therefore, the full source voltage is applied to the load.

The rheostat (fig. 9-24B) is set at 10 ohms. This resistance is in series with the 10-ohm load; therefore, the total circuit resistance is 20 ohms. The circuit current found by Ohm's law $I = E/R$, is 6 amperes. This current flows through the rheostat, and the IR drop across its terminals is 6 amperes times 10 ohms or 60 volts. This voltage drop must be subtracted

77.134

Figure 9-24.—Voltage-dropping action.

from the source voltage so that the load will be supplied with 60 volts.

This type of voltage reduction might be used to dim lights. The rheostat could be either the continuously variable type or the step type. It would control the lamp voltage as long as it was connected in series with the load.

MOTOR DRIVEN

As the name implies, a motor-driven rheostat is a variable resistor with a motor-driven arm. The motor that drives the rheostat arm may be controlled by a manually operated switch. Motor-driven rheostats are used in certain voltage regulator installations and are discussed in more detail in chapter 11 of this course. Figure 9-25 shows a simplified motor-driven rheostat being used to control the field voltage of an a-c generator.

Motor-driven rheostats are also used in certain degaussing installations which are discussed in chapter 12 of this course.

ELECTRIC BRAKES

Electric brakes find their widest shipboard application on hoisting and lowering equipment where the ability to stop the motor quickly is important. Electrically operated brakes are extensively used for that purpose. Brakes are also needed to hold the load at rest after it has been stopped.

D-C BRAKES

Brake systems used with d-c motors are divided into two groups; dynamic and magnetic. The dynamic brakes use electrical principles, and the magnetic brakes use a combination of mechanical and electrical principles.

Dynamic

Dynamic braking may be compared to the use of an auto engine to slow a car going down hill. As you may know, pressure is generated by the compression, which acts as a brake. This comparison is possible because a d-c motor, if its field remains excited while it is being driven by a load, will act as a generator and return power to the line. The generator action holds the load.

However, in an actual system that uses dynamic braking with a series d-c motor, the motor is disconnected from the line, and its armature and field are connected in series with a resistor to form a loop. The field connections to the armature are reversed so that the armature counter-voltage will maintain the field with its original polarity.

Figure 9-26 shows the connections used for dynamic braking of a series wound d-c motor. The field switching is done by switches S1, S2, and S3. The three switches are part of a 3PDT assembly and are magnetically operated from a controller described later in this chapter.

With the switch arms in position 1, the motor operates from the line. When the switch arms are in position 2, the resistor is connected in series with the field, and, at the same time, the field coil connection to the armature is reversed. Thus, as long as the armature turns, it will generate a counter-voltage, which will force current through the resistor and the series field. Although the direction of current flow through the armature is reversed (because of the counter-voltage), the direction through the series field coil is the same as it was when operating as a motor. When operating in this manner, the machine is essentially a generator that is being driven by the momentum of the armature and mechanical load. This energy is

11543

77.136

Figure 9-26.—Connections for dynamic braking of a series-wound d-c motor.

77.137

Figure 9-27.—Connections for dynamic braking of a shunt-wound d-c motor.

quickly consumed in forcing current through the resistor, and the armature stops turning.

The time required to stop the motor may be varied by using different resistor values. The lower the resistance, the faster the braking action. If two or more resistors are connected by switches, the braking action can be varied by switching in different load resistors. Usually, the same braking resistors that are used to stop the motor are also used to reduce the line voltage during acceleration. This feature has been omitted on the drawing for simplification.

When dynamic braking is used with a d-c shunt-type motor, resistance is connected across the armature (fig. 9-27).

Switches, S1 and S2, are parts of a DPDT circuit breaker assembly. When the switch arms are connected to position 2, the armature is across the line, and motor operation is obtained. When the switch arms are in position 1, the armature is disconnected from the line and connected to the resistor. The shunt field remains connected to the line. As the armature turns, it generates a counter-voltage, which forces current through the resistor. The remainder of the action is the same as described for the circuit in figure 9-26.

Although dynamic braking provides an effective means of slowing motors, it is not effective when the field excitation fails or when an attempt is made to hold heavy loads; without rotation the counter-voltage is zero, and no braking reaction can exist between the armature and the field.

Magnetic

Magnetic brakes are used for complete braking protection. In the event of field excitation failure, they will hold heavy loads. The essential parts of a d-c magnetic brake system are the brake shoes or bands, the brake wheel or drum, the electromagnet, spring mechanism, and mounting frame. The spring applies the brakes, and the electromagnet releases them.

Disc brakes are arranged for mounting directly to the motor end bell. The brake lining is riveted to a steel disc, which is supported by a hub keyed to the motor shaft. The disc rotates with the motor shaft.

The band type brake has the friction material fastened to a band of steel, which encircles the wheel or drum and may cover as much as 90 percent of the wheel surface. Less braking pressure is required and there is less wear on the brake lining when the braking surface is large.

CACII 11544

D-c brakes are operated by a solenoid which may be wound for either shunt or series connection to the line. Shunt coils are wound with a large number of turns of small wire, and series coils are wound with a small number of turns of large wire.

Normally, magnetic brakes with shunt coils do not release as fast as those with series coils. This is due to the increased inductance, L, of a shunt coil. When the shunt coil is deenergized, the collapsing field of the magnet induces a voltage in the coil, which holds the relay armature for a short time after the magnet is deenergized. Coils are wound to operate at a voltage that is lower than the line voltage to speed up the operation of a shunt type magnet. With lower voltage coils, fewer turns are required and this lowers the ratio of inductance to resistance. A resistance is used in series with the coil to drop the line voltage and prevent damage to the brake coil. Usually, the coil is wound to operate on one-half the normal line voltage, but to get extremely fast release, it may be designed to operate on voltages as low as one-tenth the normal line voltage.

Series brake coils have advantages over shunt coils. They are faster in operation because they have less inductance, are wound with heavy wire (not likely to burn out), and, because the voltage per turn is low, the insulation is not likely to break down. In addition, these coils are in series with the motor armature, and if the armature circuit opens, the brake will set. However, if the load varies over a considerable range, the armature current may not always be large enough to keep the brake released. In this case, a shunt coil is preferred. Series brakes are not in general use on naval ships.

As previously mentioned, magnetic brakes are applied when the coil is not energized. A spring or weight holds the band, disc, or shoes against the wheel or drum. When the coil is energized, the armature or solenoid plunger overcomes the spring tension and releases the brake.

A magnetic brake assembly with the various parts labeled is illustrated in figure 9-28. When the coil is energized, two armatures are pulled horizontally into the coil. The armatures are mechanically linked to the levers. The levers pivot on the pins. When the magnetic pull overcomes the pressure of the coil springs, the pressure of the brake shoes on the drum releases and allows it to turn. The drum is mechanically coupled to the motor shaft or the shaft of the device driven by the motor. The coil is connected to the voltage supply lines. The method of connecting the coil (series or parallel) is determined by the coil design.

A-C BRAKES

Brake systems used on a-c equipment perform the same work as those used on d-c systems. However, there are differences in brake construction.

Solenoid

The a-c solenoid brake is designed the same as the d-c brake (fig. 9-28), except that the brake frame and solenoid are of laminated construction to reduce eddy currents. Because the magnetic flux passes through zero twice each cycle, the magnet pull is not constant. To overcome this, shading coils are used to provide pull during the change of direction of the main flux. However, even with shading coils it is difficult to design a solenoid that is completely free from vibration and quiet in operation.

The principal disadvantage of an a-c solenoid is that it draws a heavy current when voltage is first applied. This effect is caused by the large air gap that exists before the solenoid is energized. With a large air gap, the flux density and inductive reactance, X_L, are low. Because the current is limited principally by the X_L ohms of the coil, the inrush current is high as the air gap closes. When the solenoid is operated, the flux density and X_L ohms increase, thereby lowering the current to the operating value. In general, a-c solenoids are used only for small brake applications. It is possible, however, to use polyphase solenoids to brake larger motors.

Torque Motor

The torque motor brake uses a specially wound polyphase squirrel-cage motor in place of the brake release solenoids. The motor may be stalled without injury to the winding and without drawing heavy currents. The mechanical arrangement of a torque-motor brake assembly and the ball-jack assembly are given in figure 9-29.

The mechanical connection between the torque-motor shaft and the brake operating

11545

winding. The current flowing through the control windings of the saturable reactor assembly determines the amount of output signal developed.

The center winding or primary of the saturable reactor assembly is excited by 115 volts a.c. The coupling from the primary to the output or secondary windings is controlled by the conduction through the control windings. The control winding with the least current flow allows the greatest coupling from primary to secondary. The output windings are wound in series opposing. Capacitors C9 and C10 serve to filter the a-c component and give a fairly constant current flow through the control windings.

In the case cited previously, since V2 (B) is conducting the least, the saturation of the bottom section of T2 is less than that of the top section. Under these conditions the voltages developed in the bottom output winding far exceed those developed in the top winding. The polarity of the voltage taken from the output of the saturable assembly will be the same as that from the bottom winding. This voltage is applied to the control winding of the azimuth torque motor.

The rotor of the AZIMUTH TORQUE MOTOR is mechanically connected to the secondaries of the azimuth sweep synchro and the rotor of the azimuth followup synchro. The motor then drives the followup synchro rotor to a new null relationship with the rotor of the transmitting synchro, or zero set synchro, depending upon the position of K2101. One secondary winding of the AZIMUTH SWEEP SYNCHRO (resolver) is connected to the vertical winding of the deflection system, and the other is connected to the horizontal deflection winding.

Refer to figure 17-36 for a descriptive analysis of changes in the azimuth stabilization system when the aircraft heading is changed. With the antenna stopped in the dead ahead position, as shown in (A), an error signal is

Figure 17-36. —Analysis of changes in an azimuth stabilization system.

1152

77.138

Figure 9-28.—Magnetic brake assembly.

lever is through a device called a "ball jack" (fig. 9-29B), which converts the rotary motion of the torque-motor shaft to a straight line motion.

When power is applied to the torque motor, the shaft turns in a clockwise direction. The thrust element ① in the jack pushes against the operating lever ② in figure 9-29A, and the upward movement of the jack screw ③ (fig. 9-29B) moves the operating lever to release the brake. As soon as the brake is fully released, the torque motor stalls across the line. This holds pressure against the spring ④ in figure 9-29A, and keeps the brake released.

When the voltage supply to the torque motor is opened, the torque spring forces the brake shoes against the brake wheel. This stops and holds the motor shaft.

The torque motor brake can be released manually by raising lever ②. However, if the

11546

77.139

Figure 9-29.—Torque-motor brake and ball jack assembly.

lever is not held manually in the UP position, the brake will be applied.

DISC BRAKES

The disc brake is arranged for mounting directly to the motor end bell. The brake lining is riveted to a steel disc, which is supported by a hub keyed to the motor shaft. The disc rotates with the motor. When the brake is set, a spring pulls a stationary steel member into contact with the rotating disc. Although brakes have been built with a number of discs, the use of more than one disc increases the chance of the brake's dragging when it is released.

MOTOR CONTROLLERS

A motor controller is a control device or group of control devices designed to control the operation of the motor to which it is connected. Motor controllers may have different enclosures as required by the location, atmospheric conditions, or presence of explosive vapors or liquids in the vicinity of the controller. Motor controller enclosures may be open, dripproof, spraytight, watertight, submersible, or explosionproof. The open type of motor controllers are found primarily on older auxiliary ships where they are used to control the numerous deck winches. In some installations several open type controllers may be grouped together in one space, such as all the winch controllers for one cargo hold.

The other types of controller enclosures are found on all types of ships. The more common forms of protection provided by motor controllers are low voltage protection, low voltage release, low voltage release effect, overload protection, short circuit protection, full field protection, and jamming (step back) protection.

D-C CONTROLLERS

Because of the inherent characteristics of a-c and d-c motors, d-c motors require different controls than do a-c motors. Except for small motors or motors of special design, direct current motors are not started on full line voltage.

D-c controllers insert a resistance in series with the motor armature during the starting cycle to cut down the heavy initial current that would flow in the absence of armature counter-voltage (CEMF). As the motor accelerates, the resistance is taken out of the armature circuit, and, at normal speed, the motor operates directly across the line. A d-c motor and controls are illustrated in figure 9-30, the sequence of controller operation is as follows.

When the START button is pressed, the path for current is from line terminal L2 through the STOP button, the START button, and the line contactor coil LC to line terminal L1. Current flowing through the line contactor coil LC causes the contactor armature to pull in and close the line contacts, LC1, LC2, LC3, and LC4.

When contacts LC1 and LC2 close, motor-starting current flows through the series field, the armature, A, the series relay coil, SR, the starting resistor, R, and the overload relay coil, OL. At the same time, the shunt field winding, SH, is connected across the line and establishes normal shunt field strength. When contacts LC3 close they prepare the circuit for the accelerating contactor coil, AC. Contacts LC4 close the holding circuit for the line contactor coil, LC.

11547

77.140

Figure 9-30.—Schematic of d-c control connections to motor.

The armature current flowing through the series relay coil (SR) causes the armature to pull in; opening the normally closed contacts, SR. As the motor speed picks up, the armature current drawn from the line decreases. At approximately 110 percent of normal running current, the series relay current is not enough to hold its armature in; therefore, it drops out and closes its contacts, SR. These contacts are in series with the accelerating relay coil, AC, and cause it to pick up its armature, closing contacts AC1 and AC2.

Auxiliary contacts AC1 on the accelerating relay keep the circuit to the relay coil closed while the main contacts, AC2, short out the starting resistor and the series relay coil. The motor is then connected directly across the line, and the connection will be maintained until the STOP button is pressed.

Controllers for large d-c motors have two or more stages of acceleration. These stages may employ series-lockout contactors of the type discussed previously (figs. 9-17 and 9-18).

Reversing

In certain installations it is necessary to reverse the direction in which a motor rotates. In a d-c motor this is accomplished by reversing the connections of the armature with respect to the field. The reversal of connections can be done in the motor controller by adding two electrically and mechanically interlocked contactors.

A motor reversing connection is shown in figure 9-31. Note that there are two START buttons—one marked, START EMERG FORWARD and the other marked, START EMERG REVERSE. These buttons serve as master switches; and the desired motor rotation is obtained by pressing the proper button. Either (START-EMERG) button is used as a start switch by momentarily pressing it. The same button is also used as the emergency run button by holding it in the closed position, which bypasses the overload contacts, OL.

With the exception of manual controllers the emergency run feature, holding the start button in to shunt the OL contacts, is not included on auxiliary equipment aboard ships built since 1948. In newer construction certain essential equipments have emergency run features but in a different form.

In some cases the emergency run feature is obtained by holding in the overload trip reset pushbutton during emergency operation. Regardless of the type of emergency run feature, a motor should never be operated by the emergency run button except when an actual emergency exists. When operating under an

77.141

Figure 9-31.—Motor reversing connections

emergency condition there is great danger of damage to the motor, cables, and controller. Using figure 9-31, it is easy to see the reversal of the armature connections as explained in the following paragraph.

Assuming that the FORWARD button has been pressed, the line voltage will be applied through the button to the forward contactor coil (F) which pulls in its armature and closes its normally open contacts in the motor armature circuit (F1, and F2), the forward contactor holding circuit (F3), the line contactor operating circuit (F4), and opens its normally closed contacts (F5) in the reverse contactor circuit. The normally closed contacts (F5) are an electrical interlock. With the forward contactor operated, the reverse contactor cannot be energized. After the line contactor is energized, acceleration is accomplished in the manner described for the previous starter. Now press the stop button and deenergize all contactors, then press the REVERSE button and go through the circuit in the reverse direction, note the armature circuit reversal as contacts (R) close.

Speed Control

It is often necessary to vary the speed of a d-c motor. One way to accomplish this is to

11220
11549

vary the strength of the shunt field by connecting a rheostat in series with the shunt field. Figure 9-32 illustrates how a rheostat is added to the basic controller circuit to obtain varying speed.

If resistance is added in series with the field, the field will be weakened and the motor will speed up. If the amount of resistance in series with the field is decreased, the field strength will increase and the motor will slow down. On auxiliary ships numerous controllers for ventilation blowers and auxiliary pumps are equipped with rheostats for varying the motor speed. In some installations the rheostat is mounted adjacent to the controller, while in others it may be some distance from its associated controller.

A-C CONTROLLERS

The majority of a-c motors are started on full voltage by action of a contactor. The exceptions are large horsepower motors in some applications and others of special design, which start on reduced voltage and, after partial speed is acquired, are switched to full voltage by the actions of a controller.

Reduced voltage for starting a-c motors can be provided by one of the following methods; (1) primary resistor or secondary resistor, (2) primary reactor, and (3) auto transformer or compensator.

The primary resistor controller inserts resistors in the primary (stator) circuit of an a-c motor for starting or for starting and speed control. The secondary resistor controller inserts resistors in the secondary (rotor) circuit of wound rotor type motors for starting or speed control.

The primary reactor controller inserts a reactor in the primary circuit of an a-c motor during starting and subsequently short circuits the reactor to apply line voltage to the motor.

77.142

Figure 9-32.—Field rheostat connected to control motor speed.

11550

A compensator or autotransformer controller starts the motor at reduced voltage through an autotransformer, and subsequently connects the motor to line voltage after acceleration. The compensator controller may be either the open-transition or closed-transition type. The open-transition type cuts off power to the motor during the transition period of shifting the motor from the autotransformer to direct connection with full line voltage. In the short time when it is disconnected, the motor may coast and slip out of phase with the power supply. When the motor is then connected directly to the line, a high transition current may result. The closed-transition type of controller keeps the motor connected to the power supply at all times during the transition period. In this method the motor does not fall out of phase and therefore there is no high transition current.

A single-phase autotransformer has a tapped winding on a laminated core. Normally, only one coil is used on each core, but it is possible to have two autotransformer coils on the same core.

Figure 9-33 shows the connections for a single-phase autotransformer being used to step down voltage. Part of the winding, that between a and b, is common to both primary and secondary and carries a current that is equal to the difference between the load current and the supply current.

77.143

Figure 9-33.—Single-phase autotransformer.

Any voltage applied to the terminals, a and c, will be uniformly distributed across the winding in proportion to the number of turns. Therefore, any voltage that is less than the source voltage can be obtained by tapping the proper point on the winding between terminals a and c.

One commercially available autotransformer is the Variac and is designed so that a knob-controlled slider makes contact with wires of the winding in order to vary the load voltage.

The positive directions for current flow through the line, transformer winding, and load are shown by the arrows in figure 9-33. Note that the line current is 2.22 amperes and that this current also flows through the part of the winding between b and c. In the part of the winding that is between a and b, the load current of 7 amperes is opposed by the line current of 2.22 amperes. Therefore, the current through this section is equal to the difference between the load current and the line current. If you subtract 2.22 amperes from 7 amperes you will find the secondary current is 4.78 amperes.

Autotransformer Starter

Two common uses for autotransformers are to start 3-phase induction and synchronous motors and to furnish variable voltage for test panels. Figure 9-34 shows an autotransformer motor starter, which incorporates starting and running magnetic contactors, an autotransformer, a thermal overload relay, and a mercury timer to control the duration of the starting cycle.

The autotransformer is a dual unit with separate windings on the outside legs. The windings are connected in open delta to supply reduced voltage to a 3-phase motor during the starting period. Each winding is tapped to provide starting voltages at the motor of 50 percent, 65 percent, or 80 percent of the line voltage. It is possible to change the connections to the transformer taps to get higher or lower starting voltage. It is necessary to select the tap for the desired starting voltage when making the original connections.

A complete schematic diagram of a motor starter using autotransformers as well as other control devices is given in figure 9-35. Because a number of separate controls are shown in schematic form, the action will be traced from the time the START button is pressed.

77.144

Figure 9-34.—Autotransformer motor starter.

77.145

Figure 9-35.—Schematic of motor starter using autotransformers and other control devices.

This control is a spring-loaded button, which completes the circuit between two contacts.

The START button, when pressed, completes the circuit from L1 and the button contacts through the normally closed contacts CR1 and MR4, and through the starting coil MS to L2. When the starting coil, MS, is energized, it attracts an armature, which operates seven contacts. Four of these contacts (MS1, MS2, MS3, and MS4) connect the autotransformer in open delta across the line.

The fifth contact, MS5, completes the holding circuit to the starting coil. The holding circuit is from L1 through the STOP button, to normally closed contacts 10L and 20L, through contact MS5, to normally closed contacts CR1 and MR4, and then through coil MS to L2.

The sixth contact, MS6, completes the circuit to the timer relay, TR. This circuit path is from L1 through the STOP button, through the normally closed contacts 10L and 20L, through contact MS6, and through the timer relay coil TR to L2.

The seventh contact, MS7, is normally closed, and when relay MS operates, it opens the circuit to the coil of motor running contactor, MR, so that MS7 acts as an electrical interlock. Thus, contact MS7 prevents coil MR from being energized when MS is operated. This action prevents a portion of the autotransformer winding from being short-circuited by contacts MR1 and MS1 or MR3 and MS3. After a time interval for which the timing relay is set, the mercury timer, TR, closes the circuit to the control relay, CR, governing the running contactor, MR.

The control relay contacts, CR1 open the holding coil circuit to the main starting coil, MS, permitting the starting contactor to open. Contacts CR2 close and energize the holding circuit for relay coil CR. Contacts CR3 close in preparation for energizing the running contactor coil, MR.

During the transition from reduced voltage to full voltage, relay MS opens and temporarily disconnects the transformer and motor from the circuit. During this time the motor is free-running with no connection to the line. However, this interval is of short duration because the opening of MS completes the circuit to the main running coil, MR, through the seventh or interlock contact, MS7. The MR coil then closes

11552

contacts MR1, MR2, and MR3 to connect the motor directly across the line. Electrical interlock MR4 opens to prevent the starting coil, MS, from being energized at the same time that MR is energized.

The starter previously described is an OPEN TRANSITION type because the motor is disconnected from the line during the transition from a low (starting) voltage to line (running) voltage.

Across-The-Line Controllers

Most a-c controllers used aboard ship are across-the-line controllers. Figure 9-36 shows a type of across-the-line controller that is presently being put into service aboard surface ships and submarines. It provides greater resistance to mechanical shock and is smaller in size for the same horsepower than previous models. The contactors (fig. 9-37) are available in five sizes—0 through 4 (designed for 5-10-25-50 and 100 hp). The contactors are essentially similar in appearance but vary in cubical size.

Reversing

Certain equipment, such as elevators, lathes, and hoists, requires a driving motor that can be reversed. It has been explained how d-c motor armature rotation may be changed by reversing the connections to either the field or armature winding. The reversal of an a-c (3-phase) induction motor is accomplished by interchanging any two of the three leads to the motor. The connections for an a-c reversing-type controller are illustrated in figure 9-38. The STOP, REVERSE, and FORWARD pushbutton

Figure 9-37.—Size O contactor for 5 horsepower motor.

77.148

Figure 9-38.—A-c reversing controller.

controls are all of the momentary-contact type. Note the connections to the REVERSE and FORWARD switch contacts. The circles with F and R inside represent contactor coils.

If the FORWARD pushbutton is pressed (solid to dotted position), coil F will be energized and will close its holding contacts, FA. These contacts will remain closed as long as coil F is energized. When the coil is energized, it closes line contacts F1, F2, and F3, which applies full line voltage to the motor. The motor then runs in a forward direction until the voltage supply is interrupted.

If either the STOP button or the REVERSE button are pressed, the circuit to the F contactor coil will be broken and the coil will release and open line contacts F1, F2, F3, and holding contact FA.

If the REVERSE pushbutton is pressed (solid to dotted position) coil R will be energized and will close holding contacts RA and line contacts R1, R2, and R3. Note that R contacts reverse the connections of lines 1 and 3 to motor terminals T1 and T3. This causes the motor rotor to rotate in the reverse direction. The F and R contactors are mechanically interlocked to prevent both being closed at the same time.

Momentary contact pushbuttons provide low voltage protection with manual restart in the circuit shown in figure 9-38. If either the F or R operating coil is deenergized, the contactor will not reclose and start the motor when voltage is restored unless the FORWARD or REVERSE pushbutton is pressed. The circuit arrangement of the pushbuttons constitutes an electrical interlock that prevents energizing both coils at the same time.

Speed Control

When it is desired to operate at different speeds while using an a-c motor, you may use a circuit such as that in figure 9-39. Two speed operation is desirable for anchor and cargo hoists, ventilators, and deck winches.

An a-c inductor motor that has been designed for two-speed operation may have a single winding or two separate windings, one for each speed. In figure 9-39 the motor slow winding is connected to terminals T1, T2, and T3. The motor fast winding is connected to terminals T11, T12, and T13. Overload protection is provided by the S-OL coils and contacts for the slow winding and the F-OL contacts and coils for the fast winding.

The control pushbuttons are of the momentary contact type. Pressing the FAST pushbutton (solid to dotted position) closes the fast contactor by energing coil F. This coil remains energized, after the pushbutton is released, through holding contacts FA. The coil, F,

11554

77.149

Figure 9-39.—Speed control circuit for an a-c motor.

closes main-line contacts F1, F2, and F3, which apply full line voltage to the motor fast winding. The motor will then run at fast speed until coil F is deenergized.

Pressing the SLOW pushbutton closes the slow contactor by energizing coil S. The coil remains energized, after the button is released, through holding contacts SA. The coil, S, closes main-line contacts S1, S2, and S3, which apply full line voltage to the motor slow winding. The motor will then run at slow speed until coil S is deenergized. The F and S contactors are mechanically interlocked to prevent both being closed at the same time.

CONTROLLER MAINTENANCE AND TROUBLESHOOTING

To ensure proper mechanical operation and to decrease the possibility of failure at critical times, keep the motor control equipment clean.

On ships that have the 3-M System in effect, controller maintenance is a scheduled routine. However, since all ships do not as yet have the 3-M System installed, the following maintenance coverage is given.

The first step in an adequate maintenance program should be a thorough inspection of the equipment after it is installed and before it is operated electrically. An inspection of this type should include cables, connections, fuses, and equipment mountings. All oil and grease fittings should be checked to make sure the equipment has been lubricated.

Most motor control equipment failures are due to mechanical faults, not to electrical troubles. Dirty equipment, improperly placed parts, and parts that bind or stick are all basic mechanical faults that can cause coil burnouts, welded contacts, and circuit overloads.

The presence of foreign material will cause binding of latches, plungers, armatures, and lever mechanisms, which, in turn, will lead to coil burnouts, contact burnouts, short circuits between phases, and other electrical failures. The foreign material may be dust, dirt, gum, filings, grease, moisture, and rust or corrosion. A regular cleaning schedule should be followed to ensure dependable operation.

Slow making and breaking of the load circuit may be caused by binding of the armature, plunger, or lever mechanism. To eliminate this condition, remove rust, gum, and filings from the shafts, bearings, or guides. Shafts and bearings should be lubricated with two drops of light oil (S.A.E. 10) semiannually.

Insulation breakdowns are often caused by metal filings or excessive moisture. Short circuits across insulating barriers, grounded circuits, and high voltage breakdowns can often be avoided by regular cleaning.

The ability to make a fast analysis of conditions when faults develop is not acquired overnight. You must study individual circuit controls and then determine which part of section could, if defective, cause the trouble.

In simple circuits where the control is a simple make and break contact arrangement, motor stoppage could be due to a lack of voltage (generator failure, or an open or shorted supply line), a defective contactor (not closing or broken), or a defective motor.

Simple voltage tests at the controller input and output terminals will show if voltage is available from the line and if the contacts are in good condition. Of course, the contacts must be closed when the output terminal test is made. Voltage present at the controller output indicates that the power source is working and that the contactor is closing the circuit. These two possible trouble spots are therefore eliminated. The remaining possible trouble spots are the leads between the controller and the motor. A

11555

applied to the true bearing amplifier which causes the azimuth torque motor to turn. The sweep secondaries are then driven in a direction corresponding to the change in the transmitting synchro rotor, as shown in (B). When the aircraft changes its heading, the sweep position on the PPI-scope will change accordingly.

TILT STABILIZATION

The purpose of TILT STABILIZATION is to stabilize the tilt angle of the antenna of a radar system with respect to the earth. If the antenna is left unstabilized, when the aircraft changes its flight angle the antenna follows this change. If the antenna is dead ahead with respect to the aircraft and the plane begins a climb, the antenna will point up, thus losing targets. If, on the other hand, the antenna is pointing to port or starboard and the aircraft rolls to either side, the target returns will again be lost. If the antenna is stabilized with respect to the earth then the target loss, due to changes in the attitude of the aircraft, will be minimized. For example, assume that the antenna is pointing dead ahead in relation to the aircraft and the aircraft goes into a climb; if the antenna is stabilized, it will tilt down and maintain a constant angle with respect to the earth. The same holds true if the antenna is pointing to port or starboard and the aircraft is rolling; the antenna will tilt up or down, maintaining the constant reference with respect to the plane of the earth.

The stabilization range of the radar set which will be used for this explanation is such that if the TILT control is set for 0 the beam is maintained at this angle for aircraft pitch or roll up to plus 30° or minus 30°. If the TILT control is set for other beam angles, these limits vary accordingly.

The tilt stabilization system consists of a gyroscope, servoamplifier, resolver synchro, manual-tilt synchro, tilt-torque motor, damping-signal generator, and the followup synchro. (A diagram of this system is shown in figure 17-37.) The gyroscope unit is separately mounted on the aircraft structure, and the resolver synchro and the servoamplifier are mounted on the antenna-assembly frame. The tilt-torque motor, damping-signal generator, and followup synchro are contained in the tilt-servo unit mounted on the rotary section of the antenna assembly. The manual-tilt synchro is mounted in the radar set control box.

Stabilization is effected by the use of two signals, the resolver-synchro signal and the manual-tilt synchro signal. Separate pitch and roll signals originating in the gyroscope unit are combined in the resolver synchro to produce the single resolver-synchro signal. The manual-tilt synchro signal originates in the followup synchro and provides the tilt stabilization system with continuous information as to the tilt angle of the reflector. This signal passes through the manual-tilt synchro in the radar set control box where it is modified according to the setting of the TILT control. The resolver-synchro signal and the manual-tilt synchro signal, which differ in phase by 180°, are combined at the input of the servoamplifier, and the amplifier resultant, or error signal, is used to control the tilt-torque-motor in correcting the tilt angle of the reflector.

Gyroscope Unit

The gyroscope unit contains the gyro, with its drive motor, erecting mechanism, motor-driven caging and uncaging mechanism, and two synchros. The gyro, powered by a 26-volt, 400-cycle, 3-phase induction motor, establishes true vertical. The caging and uncaging mechanism is electrically operated, and is manually controlled by the GYRO switch on the radar set control. When caged, the gyro is clamped in an approximately vertical position with respect to its housing. CAGING OF THE GYRO prevents it from being damaged when the aircraft is engaged in maneuvers involving pitch or roll in excess of 60°. The gyro develops a normal operating speed of 18,500 rpm; when it is UNCAGED, the rolling-ball type ERECTING mechanism brings the gyro to true vertical and maintains it in this position. The gyro should be uncaged when in use and caged when the equipment is turned off. Although the GYRO switch may be in the UNCAGE position, the gyro is automatically caged when the POWER switch is turned off. After the equipment is turned on, the gyro remains caged during the warmup period of approximately 3 minutes, after which time the operation of the caging mechanism is dependent upon the position of the GYRO switch. The schematic diagram of the gyroscope unit is shown in figure 17-38.

1153

measurement for voltage at the motor terminals will show the condition of the leads. If voltage is present at the motor terminals and the motor does not run, the motor must be defective. As you gain experience in troubleshooting, you will develop your own testing techniques.

No matter how complex a complete circuit may appear, each individual section can be broken down into three parts: the source of voltage; the load (motor, relay coil, or other device); and the wires between the source and the load. Make it a habit to trace circuits when you encounter them. Start at one of the voltage supply terminals and then trace through the circuit or diagram to the other terminal. Once you are able to trace a circuit through on a diagram, you will find it easier to trace actual wiring. Eventually, you will find yourself forming a mental picture of a schematic diagram as you trace wiring. However, it takes a great deal of practice so don't become discouraged if you cannot trace a circuit the first time you try. You should find Blueprint Reading and Sketching, NavPers 10077 (revised), helpful.

There are times when a motor will fail to start and no signs of trouble will be readily apparent. In such cases, operate the overload reset button and again press the start button. Listen for the sound of the main contactor closing. If there are no results, press the stop button and check to determine if power is available at the input terminals of the controller. If power is available, the trouble is in the section from the controller input to the contact operating means (relay coil or leads). If no power is available, check the supply line and the associated fuses.

If the motor stopped because of tripping of the overload relay, and the relay tripped again after being reset, some possible causes of the overload are:

1. Jammed machinery (frozen bearings or foreign material in gears).
2. Overheated or stiff bearings in motor or motor-driven device.
3. Blown fuse in the supply circuit, causing single phasing of a 3-phase supply.

If no apparent cause for overload tripping can be found, the motor current should be carefully checked with an ammeter and the measured current compared with current value marked on the motor nameplate, the controller or overload relay coil or heater rating, and the current values specified on drawings for the equipment. Many overload relays have an adjustment, which allows the trip settings to be adjusted and thus takes care of minor variations. Any changes should be made in small steps in order for the relay to give maximum protection to the motor.

Many equipment failures can be prevented by correcting possible troublemaking conditions as soon as they are discovered. For example, if you notice worn insulation on a wire, protect it by taping the worn spot as soon as possible. If moisture has accumulated in an outlet or switch box, dry it out before trouble develops. By correcting conditions that are potential trouble spots, you can save lost time and make your job easier.

CONTACT MAINTENANCE

All controller contacts should be kept in good electrical condition. Determine the kind of metal used for the contacts, whether copper or silver, and apply applicable procedures outlined in chapter 8 of this training manual for maintenance of the kind of contact metal in use.

A troubleshooting chart is given in table 9-1. Contact burnouts or overheating of contacts may be due to foreign matter on the contact surfaces. Generally, foreign matter can be removed by using a cloth moistened with an approved cleaner. Where oxides or other corrosions are present, they can be removed by smoothing over the contact surfaces, using a fine file or 00 grade sandpaper.

PERIODIC TESTS AND INSPECTIONS

Controllers for motors and the associated equipment should be inspected monthly. During this inspection you should:

1. Disconnect the device or apparatus from its source of power.
2. Open the cover of the enclosure.
3. Make a visual check for:
   a. Dirt, oil, grease or moisture on component parts on or in the enclosure.
   b. Burned or worn contacts, charred insulation, or varnish extrusions.
   c. Torn gaskets, bent or missing cover bolts, corrosion, or rust.
4. Check manually for:
   a. Bind in plungers, armatures, fingers, levers, and other moving parts.
   b. Loose connections, parts, and cotter pins.

11556

Table 9-1.—Troubleshooting Chart for Contacts

TROUBLE	CAUSE	CORRECTION
Burnouts	1. Short circuits or grounds*	1. Remove grounds or shorted conditions
	2. Overheating	2. Increase low contact pressure, remove dirt, oil or grease, remove oxides or sulfides
	3. Slow "breaking"	3. Eliminate bind
	4. Low lead dimension	4. Renew contacts
	5. Excessive lead dimension	5. Reduce lead dimension
Excessive Wear	1. Excessive jogging or inching	1. Do not jog or inch controllers unnecessarily
	2. Faulty blowout assembly or arc shield	2. Replace or repair blowout coil, eliminate shorted turns
	3. Excessive overloads*	3. Eliminate cause—check current readings
	4. Slow "breaking"	4. Remove bind of parts
	5. Excessive filing	5. Do not dress or file the contacts unnecessarily
Overheating	1. Oil or grease	1. Remove with methyl chloroform
	2. Copper oxides	2. Remove with a fine file or sandpaper
	3. Low spring pressure	3. Increase pressure or replace spring
	4. Silver sulphides	4. Remove using fine sandpaper or a fine file
	5. Loose contacts	5. Tighten
Welding or Sticking	1. Ground or excessive overload*	1. Eliminate cause—check current readings
	2. High spring pressure	2. Reduce pressure
	3. Low voltage	3. Increase
	4. Slow "making" or bind	4. Remove bind
Excessive Arcing or Sputtering	1. Short circuit or ground	1. Remove grounded or shorted circuit
	2. Binding parts	2. Eliminate bind of parts
	3. Faulty blowout assembly	3. Replace or repair blowout coil, eliminate shorted turns
	4. Excessive lead dimension	4. Reduce to increase contact gap

*WARNING: Short circuits or grounds in the associated equipment necessitate a thorough inspection of the controller, as the contacts may be damaged by these conditions.

5. Check for grounds on both the main circuit and the pilot circuit.

6. If permissible, connect the equipment to a source of power and operate it in a normal manner.

a. Check for proper operation.

b. Check for excessive noise.

7. Shut off the machine and close the cover. Then tighten the cover bolts or screwpins so that the cover is held securely in place.

In addition to regular monthly test inspections, a more complete inspection should be made semiannually. The following tests should be made:

1. Check all contacts for excessive wear, proper dimensions, and proper spring pressure. If necessary, remove contact hoods or arc shields in order to reach the contacts.

2. Clean all parts thoroughly. Disassemble or partially disassemble the device, when necessary, for proper cleaning.

3. Lubricate all shaft bearings with two drops of lightweight (S.A.E. 10) oil. DO NOT LUBRICATE CONTACTS, PLUNGERS, AND

82-11557

POLE FACES OR USE EXCESSIVE QUANTITIES OF OIL ON THE SHAFT BEARINGS.

4. Check the mechanical and electrical adjustments of each device. Make any necessary readjustments.

Of course, the regular monthly and semiannual inspections do not eliminate the need for careful observation during the time the equipment is operating and the need to correct conditions that could cause trouble as soon as they are noticed.

During periodic inspections of motor controllers, or at least once a year, the overload relays should be examined to ascertain that they are in good mechanical condition and that there are no loose or missing parts. The size of the overload heaters should be checked to determine that they are of the proper size indicated by the motor nameplate current and heater rating table. Proper allowance should be made for short-time and intermittent duty motors by using undersized coils. Any questionable relays should be checked for proper tripping at the next availability and repaired if necessary. Each relay should be checked for tripping time at 300 percent rated current by a naval shipyard at intervals not exceeding 4 years.

SAFETY PRECAUTIONS

One of the first things a prospective EM should learn is that electricity is potentially a killer! A conductor carrying several hundred volts is no different in appearance that a conductor disconnected from a source of voltage. The lethal voltage that may be present on the wire has no odor and makes no sound. Yet, under certain conditions, it can snuff out your life.

If properly handled, however, electricity is not dangerous. Almost all deaths caused by electric shock could have been prevented if a few simple rules had been followed. Therefore, you should memorize these rules and then ALWAYS FOLLOW THEM.

The first rule is to always assume, until tests prove differently, that all conductors are hot. Do not assume that low voltage circuits (115 volts or less) are not dangerous. A number of shipboard fatalities have been reported due to contact with 115-volt circuits. Shipboard conditions are particularly conducive to shock because of the metal structure of the ship. Also, the body resistance may be low due to perspiration or damp clothing.

Do not lose your sense of caution because you are in a hurry to get the job done. Often taking time to make certain will save time. Except in cases of emergency, never work on an energized circuit. Safety precautions for the special cases are outlined later in this section. All circuits must be considered as energized until a personal check has been made to see that the switch has been opened and tagged and that the circuit has been tested with a voltmeter or voltage tester.

Navy specifications for portable tools require a separate ground wire, which grounds the frame of the tool. Normally, this is taken care of by using a 3-wire cable with a special plug and receptacle. Two of the wires in the cable connect the tool to the line. The third wire, distinctively marked, is connected to the tool frame at one end and to the ground contact of the plug on the other end.

Where grounded receptacles have not been installed or where the tool does not have the internal ground wire connection, the tool should be grounded by obtaining an additional wire and connecting it between the tool frame and the ship's metal structure.

Portable cables should be carefully selected and maintained. They should be of the proper length and cross-sectional area. Spliced portable cables are extremely dangerous and should not be used unless the emergency justifies the risk involved.

Always use a fuse puller when changing fuses. This precaution is necessary because one end of a fuse is hot, and, in some cases, both ends are hot even though the fuse is blown. When a fuse is blown, it should be replaced with a good fuse having the same rated voltage and current capacity.

Extreme care should always be taken to ensure safety for the operator and other personnel when operating switches and circuit breakers. Before closing any circuit breaker or switch, be sure that:

1. The circuit is ready with all equipment connected to it in condition to be energized.
2. Men working on the circuit are clear and are notified that it is to be energized.
3. All circuit protective devices (fuses, circuit breakers, and overload protectors) are in good working condition.
4. Only one hand is used to operate a circuit breaker or switch unless operating

arrangements specifically provide for the use of both hands. Keep the other hand clear because metal parts of the circuit breakers or switches may be at circuit potential.

5. For manually operated knife switches the opening or closing motion is made positively and rapidly.

Live Circuit Precautions

Military necessity may require repair or maintenance work on energized circuits. When this condition exists, extreme precautionary measures MUST BE TAKEN. Such work should be accomplished only by adequately supervised personnel fully aware of the dangers involved. Every precaution should be taken to adequately insulate the person performing the work from ground. In addition the following precautions should be taken:

1. The person doing the work should remove wristwatches, rings, watch or key chains, metal articles, or loose clothing, such as neckties or unbuttoned sleeves which might accidentally catch and throw his body into contact with live parts. All clothing and shoes should be as dry as possible.

2. Ample illumination should be provided.

3. The worker must be insulated from ground by covering nearby metal that he might contact with dry wood, rubber mats, dry canvas, or even several thicknesses of dry paper. Be sure that any material used for insulation has no holes in it and no conducting material imbedded in it.

4. Working metal tools must be covered with insulating rubber tape (not friction tape) as far as practical.

5. Insulating barriers must be provided between the work and any live metal parts immediately adjacent to the work to be done.

6. The work should be accomplished, using one hand only, if possible.

7. If the work permits, rubber gloves should be worn on both hands. If this is not possible, a rubber glove should be worn on the hand not used in handling tools.

8. Men must be stationed at circuit breakers or switches, and telephones must be manned, if necessary, so that the circuit or switchboard can be deenergized immediately in case of emergency.

9. A man qualified in first aid for electric shock should be immediately available while work is being done.

Charged Circuit Precautions

In certain cases, electrical machinery may retain a charge even though it is secured. This charge can be great enough to cause severe shock. Therefore, before touching the terminals or an apparently dead machine, discharge it to ground, using an insulated portable wire or a tool with an insulated handle.

Capacitors used to suppress radio interference and other purposes store electrical energy. Before touching the terminals of a capacitor, which is connected to a deenergized circuit or has been disconnected entirely, short circuit the terminals.

Cleaning and Painting Precautions

Never use toxic materials for cleaning in closed spaces. Carbon tetrachloride is an excellent cleaner, but extremely poisonous and dangerous to use in closed spaces. It is no longer authorized for cleaning purposes and methyl chloroform should be used in its place.

Gasoline, benzine, ether, and other similar flammable fluids should never be used for cleaning electrical equipment even though it has been deenergized. Fumes from these fluids form a highly explosive mixture when mixed with air, and a slight spark can set them off.

Because many cleaning fluids are detrimental to good commutation, they should never be poured or sprayed on commutator surfaces. Instead, any cleaner should be applied with a clean cloth, and the surface should be dried with another cloth.

Paint should never be used to refinish shafts, bearings, guides, sliding parts, magnetic pole faces, ground surfaces, contact members, or phenolic or ceramic parts.

11559 U6611

CHAPTER 10

SMALL CRAFT ELECTRICAL SYSTEMS

Small craft perform an important function in the daily routines of all naval vessels. Underway, they serve as duty life boats and must be ready at all times to operate instantly and efficiently. In port, they must be prepared to perform a variety of tasks, such as transporting stores and liberty parties. On some ships, such as troop transports, small craft are vital to the accomplishment of the ship's mission and the condition of these boats affects the condition of readiness of the ship.

The capability of small craft to carry out these services depends, to a great extent, on the assigned Electrician's Mate, who is responsible for the proper operation and upkeep of the electrical systems installed in these boats.

On certain ships you may be assigned to work on boats and batteries and actually be assigned to the boat shop. The boat shop is normally a part of the A division and in some ships the boat electricians are a part of the A division for work assignment, liberty section assignment, berthing and mustering. Regardless of the type or size of ship you are assigned to, working on the electrical systems of the ship's boats or vehicles is a challenging and rewarding job. And if you do your job well you will attract favorable attention to yourself. But as you probably know however, if the Admiral's Barge doesn't start, or the running lights on the Captain's Gig are inoperative, the boat electriciar will find himself in an embarrassing position.

The electrical systems on various types of small craft and ship's boats are too numerous to cover in detail in a single chapter. The systems covered however, are representative of those found on the majority of ship's boats and small craft. This chapter also gives a brief description on automotive electrical systems, although vehicles assigned to a ship are normally taken to a motor pool at shipyards or naval stations for periodic tuneup and preventive maintenance. While your ship is in a location that has automotive repair facilities, the ship's vehicles are no problem. It is when the vehicles are unloaded at some remote port that troubles seem to start. Therefore, the ship's Electrician's Mates should have a working knowledge of automotive electrical systems as well as of boats and small craft.

The electrical system on a typical small boat consists of the following:

(a) a battery charging generator driven from the propulsion engine.

(b) an engine starting system.

(c) a battery used both for engine starting and for supplying auxiliary loads when the engine is secured.

(d) a control and distribution panel having switches and fuses for the control and protection of circuits to auxiliary loads.

(e) cable for interconnecting the above.

(f) voltage regulator.

Figure 10-1,A shows a typical electrical system for small boats with wood or plastic hulls and a single propulsion engine. Figure 10-1,B is a typical electrical system for small boats with steel hulls and a single propulsion engine.

UNGROUNDED TWO-WIRE, 24-VOLT D-C SYSTEM

The electrical system used on Navy small boats is, generally, a two-wire, ungrounded, 24-volt d-c system. The two-wire system is, of course, a necessity on a nonconducting boat hull of wood or plastic. The steel boat hull, like the automobile chassis, makes a good electrical conductor and permits the use of a single-wire electrical system with a grounded or hull return. There are certain reasons, however, for the use of an ungrounded two-wire

11560

77.150.1

Figure 10-1.—Electrical systems for small boats, single engine installations. A.—Typical electrical system for small boats with wood or plastic hulls. B.—Typical electrical system for small boats with steel hulls (1) storage battery; (2) starting motor for propulsion engine; (3) solenoid switch (4) generator and voltage regulator; (5) propulsion engine; (6) distribution and control panel; (7) ammeter, zero center scale; (8) horn; (9) pushbutton; (10) fuse; (11) miscellaneous auxiliary loads; (12) switch.

system on steel hull boats instead of the single-wire installation.

Because of environmental conditions (exposure to salt water spray), an unwanted (accidental) ground sometimes occurs on boat electrical systems. The Navy's service experiences reveal that fewer shutdowns occur on its ungrounded two-wire systems that on the single-wire systems. As a result, every effort is made to provide a two-wire ungrounded system and the EM must maintain it in that condition. The ungrounded systems can tolerate the temporary addition of any SINGLE grounded condition, regardless of its location, because no function is affected. A variety of troubles however, may result when two places in the system become grounded. The more common troubles include blown fuses, failure to energize the starting system, or faulty operation of any device, such as horn, voltage regulator, lights, and miscellaneous auxiliary loads.

PROTECTION OF CIRCUITS

As shown in figure 10-1,A and B, fuses are normally provided only in the circuits supplying auxiliary loads such as horns, running lights, cabin lights, spotlights, and communications equipment.

All other circuits, such as the starting motor circuit, solenoid switch control circuit, battery charging circuit, and power supply to the distribution panel, are unfused. Protection of the unfused circuits is adequate because the possibility of short circuits or leakage currents has been reduced by providing the following:

1. Two-wire ungrounded electrical system instead of single-wire grounded.
2. Two-wire ungrounded electrical components of such rugged construction as to make grounding of internal wiring or terminals most difficult under normal service conditions.

11581 11965

3. Watertight components such as battery connection boxes, distribution and control panel, and starting motor solenoid switch.

4. Cables between batteries and starting motor of sufficient size to carry high inrush currents and provided with terminal lugs and end sealing to prevent penetration of moisture.

5. Splash guards for attached generators.

6. Protection of instruments such as the battery charging ammeter by providing sealed meters or a transparent splash shield.

7. Fusing of auxiliary load circuits to isolate faults in these circuits.

PROTECTIVE DEVICES

The auxiliary circuits are protected by circuit breakers or fuses. Circuit breakers are preferred, but fuses are more commonly used due to cost savings.

As shown in figure 10-1,A the positive side of the line is protected on the auxiliary circuits of wood or plastic hulled boats, whereas the steel hulled boats (fig. 10-1,B) have both sides of the line protected.

On a boat having a steel hull with a two-wire distribution system and protection in only one side of the line, malfunctioning of the electrical system could occur as follows:

1. A fault to ground on the unprotected side of the line or equipment and a second fault from the other side of the line could discharge the battery.

2. More than one leakage path to ground shorting out the fuse in the protected side of the line, and a single fault on the unprotected side of the line could overload and destroy the cable.

3. A ground on both sides of a start switch could result in false starts.

Ground detection systems are not provided on small boats, however, a degree of protection is provided on steel hulled boats by having circuit breakers or fuses in both sides of the line.

ENGINE STARTING SYSTEM

The engine starting system consists essentially of a storage battery, starting motor, and suitable controls. The engine starting system will vary, depending on whether the boat is equipped with a gasoline engine or a diesel engine. For example, a gasoline engine-driven boat includes an electrical ignition system; whereas, a diesel engine-driven boat often includes an electric air heater. The majority of small boats are powered by diesel engines due to the safety hazard of using gasoline, however some gasoline engine driven boats are in use.

Ignition systems and electric air heaters are discussed later in this chapter. Figure 10-2 shows a typical electrical systems for a steel hulled small boat with two propulsion engines. In this system (fig. 10-2) you will notice there are three switches, numbered 1, 2 and 3, which control three solenoids, also numbered 1, 2 and 3. Under normal conditions the number 1 switch is pushed to energize the number 1 solenoid which in turn energizes the starting motor M, and cranks the number 1 propulsion engine. The starting circuit for the number 2 propulsion engine is identical, using start switch and solenoid numbers 3. The purpose of the switch and solenoid numbers 2 is for paralleling the two sets of engine starting batteries in the event one set is too low to start its engine. For example, if the number 1 engine is started by normal procedure but the number 2 engine fails to start due to low batteries, it may be started by holding the number 2 switch in the closed position (to parallel the batteries) then press the number 3 switch to start the number 2 engine. The batteries for the number 1 propulsion engine should be near full charge at all times since they supply only the boat's horn and engine starting circuits.

STORAGE BATTERY

The lead acid storage battery as discussed in chapter 7 of this course provides the power source for starting small boat engines. The battery also functions as a voltage stabilizer in the electrical system, and supplies electrical power for a limited time when the electrical load exceeds the output of the boat's generator. The boat battery for a 24-volt starting system normally consists of four individual six-volt batteries connected in series. The advantages of using six-volt batteries are ease of handling the smaller batteries and easy replacement of any single battery in the event of a defective cell.

Periodic inspection of the storage battery is essential in maintaining maximum efficiency and long life of the battery. The operation and maintenance of engine-starting batteries is discussed in chapter 7 of this training course.

11562 10211

77.150.2

Figure 10-2.—Typical electrical system for small boats with steel hull and two propulsion engines.

BATTERY CHARGING GENERATORS

In order to maintain the battery in a fully charged condition, it is necessary that the discharge current be balanced by a charging current supplied from an external source, such as a battery-charging generator. If the discharge current exceeds the charging current for an appreciable period, the battery will gradually lose its charge and then will not be capable of supplying the necessary current to the electrical system.

Battery-charging generators sometimes are flange mounted on the rear of the engine and driven from the timing gear train, but usually they are cradle mounted on the side of the engine and driven by a V-belt from the crankshaft pulley. These generators are rated according to the particular application, and are designed for clockwise or counterclockwise rotation. They are supplied for use with either a 6-, 12-, or 24-volt system.

Three general types of battery-charging generators are used on small boats.

1. Belt-driven d-c generator (fig. 10-3).
2. Belt-driven alternator (fig. 10-4).
3. Diesel engine-driven alternator.

The voltage and output ratings of small craft generators vary according to the needs of the particular boats. As a general rule, the boat with the smallest electrical system has a belt-driven d-c generator.

The alternator rectifier (to be discussed later in this chapter) has been used on small boats that have a large electronic load. With the d-c generator type of operation, the battery is required to supply the power demands during the low or idle-speed condition. When the engine does reach charging speed, the period of operation is often too short to permit satisfactory charging of the battery. The boat with the largest electrical system has a separate diesel engine-driven alternator.

Figure 10-5 shows an a-c/d-c system designed to supply additional electronic and other a-c loads as well as the normal d-c loads.

11563

81.127

Figure 10-3.—Sectional view of a typical belt-driven D-C generator.

SHUNT GENERATORS

Figure 10-6 shows three different battery charging systems employing shunt generators. Figures 10-6,A and B show the externally and internally grounded types of generators as formerly used on certain small craft. As explained previously, the present practice is to use an ungrounded electrical system such as shown in figure 10-6,C.

Shunt generators require some form of regulation to control the output current and prevent the generator from exceeding its maximum rated voltage when the speed increases.

Regulators operate on the principle of inserting a control resistance in series with the generator field circuit to reduce the voltage and output of the generator as required by the operating conditions. Generators are classified as externally grounded, internally grounded, and ungrounded according to the system used to connect the control resistance in the field circuit.

The externally grounded generator (fig. 10-6,A), usually has one end of the field circuit connected to the ungrounded generator brush and the other end brought out through terminal F to ground through the regulator. Thus, the field circuit is grounded outside the generator.

The internally grounded generator (fig. 10-6,B), usually has one end of the field circuit connected to a grounded generator brush and the other end brought out through terminal F and connected to terminal A through the regulator. Thus, the field circuit is grounded INSIDE the generator through the grounded brush connection.

11564

75.178

Figure 10-4.—Typical belt-driven alternator mounting arrangement.

The ungrounded generator (fig. 10-6,C), very often has one end of the field circuit connected internally to terminal A—and the other end connected externally through terminal F and the voltage regulator to terminal A+. The essential difference between the internally grounded generator and the ungrounded generator is that in the grounded system the circuits are completed through ground (generator frame and engine); whereas, in the ungrounded system the circuits are completed through a return ungrounded wire.

Generators with the field circuits externally grounded are generally used with STANDARD regulators common to most automotive applications; whereas, internally grounded and ungrounded generators are used with HEAVY DUTY regulators. The type of generator must be determined before any generator troubles can be analyzed because the procedures for testing these generators are different.

ALTERNATORS

A belt-driven alternator is being used on certain small boats with large electronic loads. The system of using a three-phase alternator and rectifying its a-c output to charge the boat batteries and supply the d-c loads is comparable to the system found on modern automobiles. The alternator has several advantages over the d-c generator, it is smaller in size than a comparable d-c generator, requires less maintenance, and supplies charging current at idling speeds. In systems using d-c generators, the output voltage is normally too low at idle or low speeds to supply charging current.

Figure 10-7 shows a schematic wiring diagram of an alternator and its associated control unit, (normally referred to as simply the regulator).

On small boats where load requirements exceed the capacity of one (2000-watt) alternator as shown in figure 10-7, two alternators operating in parallel may be provided. Figures 10-8, A and B show the connections for parallel and single system operation, respectively. The generating system operates as though it were a conventional d-c generator and regulator.

The electrical energy taken from terminals G- and G+ (fig. 10-7) is direct current. The three-phase a-c output of the stator is fed to a rectifier bridge consisting of six silicon diodes as shown in figure 10-7. The silicon diodes are normally located in the end-bell of the alternator. The rotor of the alternator has one coil and two six-fingered rotor halves as shown in figure 10-9. This in effect is a twelve-pole rotor. Direct current (for field excitation) is supplied to the rotor coil through a pair of brushes and slip rings.

The electrical equipment is designed to operate at a specific voltage irrespective of the speed of the engine (prime mover) and the alternator. The regulator (fig. 10-10) controls the alternator output. It consists of the (1) load relay, (2) voltage regulator, (3) current limiter, and (4) feed-through capacitors to prevent radio interference.

The LOAD RELAY acts as a switch to connect the battery to the alternator system when the engine is running, and to open the circuit when the engine is not in operation. The load relay is operated by the ignition switch when a gasoline engine is employed such as in an automobile. On an automobile when the ignition switch (fig. 10-10) is turned on, it connects the load-relay coil to the battery and the contacts close.

When a diesel engine is used, the load relay may be energized through a pressure switch in the fuel oil line. Some alternators (2000-watt Navy type, fig. 10-8,B) however, are internally connected for automatic pickup of the load relay when the voltage builds up to normal value, or

Figure 10-6.—Battery-charging d-c generators.

the load relay may be energized by an external switch (for parallel operation) as shown in figure 10-8A.

Voltage Regulators

Regulators are usually employed with battery-charging generators or alternators to provide complete control of the generator voltage and output at all times. Regulators are classified as standard and heavy-duty regulators for use with externally grounded, internally grounded, and ungrounded generators.

A standard or heavy-duty regulator consists of two or more units mounted on a common base and located in the proximity of the generator. The units, or components, in a regulator usually include a cutout relay, voltage relay, and current relay. Regulators for alternator installations are discussed first, regulators as used on d-c generator installation are covered later in this chapter.

The automotive type voltage regulator (fig. 10-10) controls the alternator field strength and thereby regulates the output voltage. The point resistor and contacts are connected in series with the alternator rotor d-c field coil. The voltage regulator (VR) coil and its ballast resistor are series connected across the d-c output terminals (GND and G) of the rectifier via the CL coil. Therefore, any variation in output voltage will change the magnetic strength of the VR coil.

When the alternator speed is low and/or the electrical load is heavy, the VR coil will cause the VR armature to vibrate on the upper contact. This action periodically inserts the point resistance in the field circuit to control the output

77.178

Figure 10-7.—System schematic wiring diagram, navy type (2000 watt) alternator and control unit.

voltage. This condition is called top contact operation.

When the alternator speed is high and/or the load is light, the VR armature vibrates on the bottom contact and periodically inserts a direct short which shorts out the entire d-c field coil of the alternator. This action intermittently weakens the field magnetism sufficiently to hold the output voltage to the proper value for this load and speed condition.

The CURRENT LIMITER protects the alternator and rectifier by limiting the current output of the alternator (fig. 10-10). The current limiter (CL) coil is connected in series with the negative terminal of the rectifier and the load circuit. When the current exceeds the rating of the alternator, the CL coil will cause the CL armature to vibrate and insert enough point resistance intermittently in the d-c field to limit the output current to the proper value.

On 6-volt regulators of this type, a temperature compensator is used to adjust the voltage regulator action to different temperatures. The temperature compensator consists of a bimetalic strip, located at the spring end of the VR armature. When the temperature changes, the bimetallic strip bends thereby causing a change in the armature spring pressure.

The operation of the navy type alternator and control unit shown in figure 10-7 is basically the same as the automotive type just explained. Except for the center tapped stator winding and provisions for automatic or external switch closing of the load relay on the 2000-watt navy type (as explained previously), both regulators operate in the same manner.

Maintenance

Several different companies are manufacturing alternators and regulators for naval use. Each unit, regardless of who manufactures it, must meet certain specifications as to type of enclosure, output voltage and current, weight, size, drive, etc. In other words, you may have boats with electrical equipment from several

CA 1568

Figure 10-8.—Battery-charging alternator connection diagrams.

manufacturers doing the same job. The maintenance procedures, methods of disassembly, voltage, current, resistance values, and air gap settings of relays may be different from one type to another.

Prior to attempting any maintenance on equipment unfamiliar to you, read carefully the manufacturer's instruction manual provided with the equipment.

Battery-charging generators in small craft should be inspected periodically to obtain optimum performance. The frequency of these inspections is determined by the type of generator and the application. MRC cards are used on ships with the 3-M system installed to cover the required maintenance and inspections of small craft electrical equipments.

If a battery-charging shunt generator (fig. 10-6) does not produce rated output or if it produces excessive output and the trouble has been isolated in the generator itself, disconnect the leads from the A and F terminals and remove the generator from the engine. Then inspect the commutator and field coils to locate any visual trouble indications. If no indications of trouble are visible, conduct further tests for grounds, opens, and shorts in the generator. If the shunt generator is the externally grounded type (fig. 10-6A), remove the ground from the armature by inserting a piece of cardboard between the brush and the commutator. Test the generator for an internal ground with a megger or similar resistance-measuring device between terminal A and the generator frame. If a ground is indicated, insulate the other brush from the commutator and repeat the test. If a ground is still indicated, it will be in the field circuit. If no ground is indicated, the ground will be in the armature. To locate the ground in the armature, conduct a bar-to-bar test, as described in chapter 6 of this training course.

If a ground is not indicated in the generator, test the field for an open circuit with an ohmmeter between the A and F terminals.

If the field is not open circuited, test for a shorted field by passing normal current through the field circuit and measuring the voltage drop across each field coil. The shorted coil will be indicated by having the lowest reading on the voltmeter.

11569

2.104
Figure 10-9.—Typical rotor for small craft or automotive alternator.

If the trouble is not in the field, test the armature for open and short circuits by conducting a bar-to-bar test in accordance with the information contained in chapter 6.

Accidental internal grounding of the field circuit or an externally grounded generator will prevent normal regulation so that the generator may produce excessive output. To test for the accidental ground in the field circuit, first insulate the grounded brush from the commutator and then connect a megger between terminal A or F and the generator frame.

If the shunt generator is the INTERNALLY grounded type (fig. 10-6,B), insulate the grounded brushes from the commutator. Test the armature circuit for ground with a megger between terminal A and the generator frame. If a ground is indicated, insulate the ungrounded brushes from the commutator and repeat the test.

If a ground is now indicated it will be between the ungrounded brushes and terminal A. If no ground is indicated, the ground will be in the armature. To locate the armature ground, conduct a bar-to-bar test. To test the field circuit for a ground, disconnect the field lead from the grounded brush and connect an ohmmeter between terminal F and the generator frame. Be certain that the lead disconnected from the grounded brush is not inadvertently grounded against the generator frame.

When a ground is not indicated in the field circuit, test the field for an open circuit with an ohmmeter between the F terminal and the field lead that was disconnected from the grounded brush.

If the field is not open circuited, test for a short-circuited field by passing normal current through the field circuit and measuring the voltage drop across each field coil.

When the trouble has not been located, test the armature for open and short circuits by conducting a bar-to-bar test.

Excessive output produced by an internally grounded shunt generator may result from a short-circuited field coil. The test for this conditon is to establish normal current through the field circuit and to measure the voltage across each coil, as previously described.

If the shunt generator is the UNGROUNDED type (fig. 10-6,C), determine which brush is connected to the field winding and insulate it and the brush diametrically opposite it from the commutator. Test the armature circuit for grounds with a megger between terminal A+ and the generator frame. If a ground is indicated, it will be in the armature or the circuit between terminal A+ and the commutator. To locate a ground in the armature, conduct a bar-to-bar test.

When the trouble is not located in the armature circuit, test the field circuit for grounds with the megger between terminal A—and the generator frame. If a ground is indicated, it will be in the field winding or in the circuit between terminal A—and the field winding.

NATIONAL BUREAU OF STANDARDS-1963-A

75.178

Figure 10-10.—Schematic wiring diagram of a typical automotive type alternator and regulator.

If a ground is not indicated in the field circuit, test the field for an open circuit with an ohmmeter between terminal F and terminal A—.

If the field is not open circuited, test for a short-circuited field by passing normal current through the field circuit and measuring the voltage drop across each coil.

When the trouble has not been located, test the armature for open and short circuits by conducting a bar-to-bar test.

An UNSTEADY or LOW OUTPUT can result in any of the generators and is usually caused by a loose drive belt, or a condition of the brush rigging that prevents good contact between the brushes and commutator. Also, a rough, out-of-round, or burned commutator, high mica; or dirt in the commutator slots can cause low or unsteady output. To correct these conditions, turn down the commutator in a lathe and undercut the mica in accordance with the instructions contained in chapter 6.

A NOISY GENERATOR can be caused by a loose mounting, drive pulley, or gear. Also worn or dirty bearings, improperly seated brushes, or a bent brush holder may be the cause.

Before installing a new or repaired battery-charging, d-c generator in a boat, the generator must be POLARIZED so that it will have the correct polarity with respect to the electrical system. Failure to polarize the generator can result in burned relay contacts, a discharged battery, and even serious damage to the generator. The correct procedure to follow in polarizing a generator depends on whether the generator field circuit is externally or internally grounded, or ungrounded (fig. 10-11).

If the generator has the field circuit externally grounded and uses a standard regulator (fig. 10-11A), ascertain the polarity of the lead from the engine battery to the regulator BAT terminal. The arrows indicate the direction of electron flow (opposite to conventional current flow). In this example the polarity is negative. Insulate the generator brushes from the commutator and connect one lead from a spare battery to terminal A of the generator. The polarity of this lead must be the same as the polarity of the regulator BAT terminal (negative in this example). Momentarily touch the other lead from the spare battery to terminal F of the generator. This action allows a momentary surge of current to flow from the spare battery through the generator field to correctly polarize the generator.

If an internally grounded generator is provided with a heavy-duty regulator (fig. 10-11B), determine the polarity of the regulator BAT

STELL 11571

A EXTERNALLY GROUNDED (STANDARD) GENERATOR

B INTERNALLY GROUNDED (HEAVY-DUTY) GENERATOR

C UNGROUNDED (HEAVY-DUTY) GENERATOR

77.153

Figure 10-11.—Polarizing generator fields.

11572

terminal. In this example the polarity is positive. Insulate the generator brushes from the commutator and connect one lead from a spare battery to terminal F of the generator. Be certain that the polarity of the spare battery lead corresponds to the polarity of the regulator BAT terminal (positive in this case). Clean a spot on the generator frame to ensure a good connection and momentarily touch the other lead from the spare battery to the generator at this spot. This action allows a momentary surge of current to flow from the spare battery through the generator (frame, grounded brush, and field windings) to correctly polarize the generator.

If the ungrounded generator is provided with a heavy-duty regulator (fig. 10-11C), determine the polarity of the regulator BAT terminal (positive in this case). Insulate the generator brushes and connect one lead from a spare battery to terminal F of the generator. The polarity of this lead must be the same as that of the regulator battery lead (positive). Momentarily, touch the other lead from the spare battery to terminal A—of the generator. This action allows a momentary surge of current to flow from the spare battery through the generator field to correctly polarize the generator.

Be certain that when the generator is installed on the engine that the polarity of the leads remains the same as for the polarizing procedure. Do not attempt to polarize a battery-charging generator after it is installed in the boat because of the fire hazard. There is always the possibility of explosive vapors in a small boat, which can be ignited by the arc when the generator field is flashed.

CURRENT AND VOLTAGE REGULATOR (STANDARD)

The current and voltage regulator (fig. 10-12) is a three-unit regulator designed for use with a shunt generator with externally grounded field circuit. It consists of a cutout relay, voltage regulator, and current regulator.

The CUTOUT RELAY is used to close the circuit between the generator armature and the battery when the generator is operating at sufficient speed to charge the battery. It opens the battery circuit whenever the generator slows or stops to prevent the battery current from reversing and flowing backward through the generator. Because of this function, it is also identified as a REVERSE CURRENT RELAY, or simply, a REVERSE CURRENT CUTOUT. Its action is described in BASIC ELECTRICITY, NavPers 10086-(Revised).

This CURRENT REGULATOR has only a series coil assembled on its core (fig. 10-12). The regulator is a current-limiting device that limits the generator output and prevents it from exceeding its maximum safe value. The generator output flows through this coil at all times. The core with the coil is attached to the frame, and the hinged armature is centered above the core. The armature has a contact

77.154

Figure 10-12.—Three-unit current and voltage regulator (standard) wiring diagram.

located below a stationary contact that is connected to the generator field circuit. When the current regulator is not operating, the armature is held away from the core by the tension of a coil spring so that the contacts are closed, and the generator field circuit is completed to ground through the current regulator contacts in series with the voltage regulator contacts.

When the generator is operating and the electrical demands are heavy, the voltage may not increase sufficiently to operate the voltage regulator. Hence, the generator output will continue to increase until the generator reaches its maximum rated value at which the current relay is set. The output current flows through the series coil and produces a magnetic field that overcomes the spring tension and pulls the armature toward the core to open the contacts. This action inserts resistor R1 in the generator field circuit so that the generator output is reduced. The reduced output weakens the magnetic field produced by the series coil, and the spring tension pulls the armature away from the core to close the contacts. This action short-circuits R1, thereby strengthening the field and permitting the generator output to again increase. This cycle continues at a rate of from 50 to 200 times a second to limit the generator output to its maximum rated value.

When the electrical load on the generator is reduced, the voltage increases so that the voltage regulator operates and reduces the generator output. This action prevents the current regulator from operating. Either the voltage regulator or the current regulator operates, but not simultaneously.

A common resistor (R1) is used in the current and voltage regulator circuits (fig. 10-12), which is inserted in the field circuit when either the current or voltage regulator operates. A second resistor (R2) is connected between the F terminal of the regulator and the frame of the cutout relay so that it is connected effectively in parallel with the generator field windings.

The sudden reduction in field current, which occurs when either the current or voltage regulator contacts open, is accompanied by a surge of induced voltage in the field windings as the strength of the magnetic field changes. These surges are partially dissipated by the two resistors (R1 and R2) to prevent excessive arcing of the contacts.

CURRENT AND VOLTAGE REGULATOR (HEAVY DUTY)

The current and voltage regulator (fig. 10-13), is a three-unit regulator designed for use with the ungrounded shunt generator. It also consists

77.155

Figure 10-13.—Three-unit current and voltage regulator (heavy duty) wiring diagram.

574

Figure 17-38. —Gyroscope unit.

The PITCH and ROLL synchros in the gyroscope unit deliver signals to the tilt stabilization system in the antenna assembly in accordance with the departure of the aircraft from level flight; these signals are used to stabilize the tilt angle of the beam with respect to the horizon. The rotor winding of each synchro is excited by 26-volt, single-phase, 400-cycle a.c. When either of the rotors is displaced from the null point, single-phase voltages are induced in the stators; the phase relationships and amplitudes of these voltages are determined by the direction and degree of displacement.

The stators of the two synchros are rigidly attached to the gyro, at right angles to each other. The rotor of the pitch synchro is mounted with its shaft horizontal, and at right angles to the line of flight of the aircraft. Since the rotor is fixed with respect to the aircraft, and the stator is fixed with respect to the gyro housing, an a-c pitch signal is developed when the rotor is displaced by the pitching of the aircraft.

The rotor of the roll synchro is also mounted with its shaft horizontal, but the shaft is parallel to the line of flight of the aircraft. Since

1155

of a cutout relay, voltage regulator, and current regulator.

The internal wiring is similar for all regulators of this type, except that the internal connections vary according to whether the regulator is designed for use with a grounded (one-wire) system or an ungrounded (two wire) system (fig. 10-13).

The units in the heavy-duty regulator are similarly constructed and perform the same functions as the corresponding units in the standard regulator previously described.

The cutout relay (fig. 10-13) has a shunt coil and a series coil assembled on one core. The shunt coil and resistor R1 comprise a series circuit that is connected across the generator so that generator voltage is impressed on this circuit at all times. The series coil is connected in series with the charging circuit so that the generator output passes through it. When the generator is not operating, the armature is held away from the core by the tension of a coil spring so that the contacts are open and the circuit is incomplete between the generator and battery.

When the generator is operating and the voltage reaches the value for which the cutout relay is adjusted, the magnetic field produced by the shunt coil overcomes the spring tension and pulls the armature toward the core to close the contacts of the cutout relay and complete the circuit between the generator and the battery.

If the generator slows down, or stops, and the voltage decreases to a value less than the battery voltage, a reverse current will flow through the series coil and the mmf produced by the series coil opposes the mmf produced by the shunt coil. When the reverse current increases to the value for which the cutout relay is adjusted, the spring tension overcomes the magnetic field and pulls the armature away from the core to open the contacts and open the circuit between the generator and the battery.

The voltage regulator (fig. 10-13) has a shunt coil and a field current coil assembled on one core. The shunt coil and resistor R2 comprise a series circuit that is connected across the generator, thereby placing generator voltage across this circuit at all times. The field-current coil is connected in series with the generator field circuit when the current regulator contacts are closed so that field current passes through it. The stationary contact is assembled into a flat spring that rises slightly above the fiber mounting bracket when the contacts are closed. This arrangement provides a wiping action between the contacts as they close and open to assure better contact.

When the generator voltage is low, the armature is held away from the core by the tension of a coil spring so that the contacts are closed and the resistance is shorted out of the generator field circuit, permitting the generator voltage to increase. The external field circuit connection to the generator armature by way of the regulator (when both the current-regulator and voltage-regulator contacts are closed) is from terminal F of the generator to the field terminal of the regulator, through the field-current coil and contacts of the current regulator, through the field-current coil and contacts of the voltage regulator, to the armature terminal of the regulator, and back to terminal A+ of the generator.

When the generator is operating and the voltage reaches the value for which the voltage regulator is adjusted, the magnetic field produced by the shunt and field-current coils overcomes the spring tension and pulls the armature toward the core to open the contacts of the voltage regulator. This action inserts parallel resistors R3 and R4 series within the field circuit to reduce the generator field current and voltage. The external field circuit connection to the generator armature by way of the regulator (when the voltage regulator contacts are open) is from terminal F of the generator to the field terminal of the regulator, through parallel resistors R3 and R4, to the armature terminal of the regulator, and back to terminal A+ of the generator.

The current regulator (fig. 10-13) has a series coil and a field-current coil assembled on one core. The series coil is connected in series with the charging circuit when the cutout relay contacts are closed so that full generator output passes through it. The field-current coil is connected in series with the field circuit when the current-regulator contacts are closed (assuming that the voltage regulator contacts are also closed) so that field current flows through it.

When the generator voltage is low, the armature is held away from the core by the tension of a coil spring so that the contacts are closed, and resistors R3 and R4 are shorted out of the field circuit to permit the field current and generator output to increase. The external field circuit connection to the

372A1575

generator armature by way of the regulator (when both current-regulator and voltage-regulator contacts are closed) is from terminal F of the generator to the field terminal of the regulator, through the field-current coil and contacts of the current regulator, through the field-current coil and contacts of the voltage regulator, to the armature terminal of the regulator, and back to terminal A+ of the generator.

When the generator is operating and the output reaches the value for which the current regulator is adjusted, the magnetic field produced by the series and field-current coils overcomes the spring tension and pulls the armature toward the core to open the contacts of the current regulator. This action inserts the effective parallel combination of resistors R3, R4, and R5 in series with the field circuit to reduce the generator output. The external field circuit connection to the generator armature by way of the regulator (when the current regulator contacts are open and the voltage regulator contacts are closed) is from terminal F of the generator to the field terminal of the regulator, through resistor R5, and the field current coil and contacts of the voltage regulator, in parallel with resistors R3 and R4, to the armature terminal of the regulator, and back to terminal A+ of the generator.

Maintenance

Proper maintenance of generator controls and regulators is necessary to ensure continued satisfactory performance. This maintenance consists of periodic tests and adjustments to the various components that comprise the control or regulator. The correct airgap measurements and voltage values for these tests and adjustments are specified in the manufacturers' instructions furnished with the specific equipment. Do not attempt these tests and adjustments without first obtaining the manufacturers' instruction books.

BATTERY IGNITION SYSTEM

Ignition of the fuel-air mixture in the cylinders of a gasoline engine is initiated by an electric spark. The spark is produced by the battery ignition system that functions to step up the relatively low voltage of the battery and to deliver the high voltage to the spark plugs at the proper time. The high voltage is capable of forcing current through the high resistance set up by the pressure in the combustion chamber and across the electrodes of the spark plugs. The hot spark created across the electrodes ignites the fuel-air mixture.

A battery ignition system consists of (1) the battery, (2) the ignition coil, (3) the ignition distributor, and (4) spark plugs (fig. 10-14). The battery and generator supply the voltage and current for the ignition system. The battery is required for starting, but after the engine starts, the generator carries the ignition load.

IGNITION COIL

The ignition coil (fig. 10-15) is a pulse transformer that steps up the low battery, or generator, voltage to the high voltage necessary to jump the gaps at the spark plugs in the engine cylinders. It consists of a primary winding having a few hundred turns of relatively heavy wire, a secondary winding having many thousand turns of very fine wire (up to 100 times as many turns of wire as the primary), and a laminated soft-iron core. The secondary winding is usually wound around the soft-iron core, and the primary winding surrounds the secondary winding. This subassembly is enclosed in a laminated soft-iron shell that serves to concentrate the magnetic field.

The entire subassembly is placed in a steel case, and the remaining space is usually filled with oil to improve insulation and reduce the effects of moisture. The case is hermetically sealed with a molded insulating cap that carries two primary terminals and the high-tension terminal.

The primary circuit of the ignition system (fig. 10-14) is from the battery, through the ignition switch to the primary terminal of the ignition coil, though the primary winding, and out the other primary terminal to the distributor. When the ignition switch is in the ON position and the contacts in the distributor are closed, current flows from the battery, through the primary winding of the ignition coil, through the contacts of the distributor, and back to the battery through ground. The current produces a magnetic field around the windings of the ignition coil. When current begins to flow through the winding, self-induction occurs and prevents the current and consequently the magnetic field from reaching their maximum values instantly. A small fraction of a second (called build-up

11576

81.138

Figure 10-14.—Battery ignition system.

time) is required for this action to occur. During this time energy is being stored in the magnetic field of the coil. When the cam lobe strikes the breaker-lever rubbing block, the breaker contact points open, thereby interrupting the primary circuit.

When the breaker contacts in the distributor begin to open, the primary current tends to continue to flow because of the self-induction of the winding. If it were not for the ignition capacitor connected across the breaker contacts, current would continue to flow between the separating points. The current would form an arc that would burn the points badly and would also drain away most of the energy stored in the coil. Thus insufficient energy would be left in the coil to produce the necessary high voltage surge in the secondary.

The ignition capacitor, however, provides a path around the points during the instant they begin to separate. Thus, the capacitor acts as a storage reservoir for the energy otherwise dissipated as an arc across the points, and also as a check on the current, quickly bringing it to a stop in the primary circuit. As a result of this action the magnetic field produced by the current quickly collapses. The rapid collapse of the magnetic field in cutting the windings of the ignition coil induces a high voltage in both the primary and secondary windings. The voltage in the primary winding may reach 250 volts (further charging the capacitor); whereas, the secondary winding (which may have 100 times as many turns as the primary) may reach 25,000 volts.

The voltage normally increases to a value sufficient to produce a spark across the spark-plug gap connected to the secondary of the ignition coil through the distributor rotor, cap insert, and high tension lead. This voltage is usually from 4,000 to 18,000 volts, depending on such variables as engine speed, engine compression, mixture ratios, width of spark-plug gap, and others.

As a spark appears at the spark-plug gap, the energy in the ignition coil drains from the coil through the secondary circuit to sustain the spark for a small fraction of a second, or for several degrees of crankshaft revolution. During this interval the capacitor discharges back

8701 11577

77.156

Figure 10-15.—Ignition coil.

through the primary circuit, producing an oscillation of the current in the primary circuit during the brief interval required for the primary circuit to return to a state of equilibrium. This sequence is repeated as each lobe of the breaker cam moves under and past the rubbing block on the breaker lever to cause the contacts to close and open.

Normally, ignition coils do not require any service except to keep all terminals and connections clean and tight. If the performance of the ignition system is not satisfactory and the trouble has been isolated in the ignition coil, it should be removed and tested for open circuits and grounds.

Test the primary for an open circuit with an ohmmeter between the two primary terminals. Test the secondary for an open circuit with the ohmmeter between the high-tension terminal and either one of the primary terminals.

Test the primary for a ground with a megger between a primary terminal and the container (ground) of the ignition coil. Test the secondary for a ground with the megger between the high-tension terminal and the container.

The test for grounds does not usually apply to the secondary windings of ignition coils used with two-wire (insulated) systems because one end of the secondary winding is grounded to the metal container. However, this ground test does apply to the primary windings of ignition coils used with two-wire systems.

IGNITION DISTRIBUTOR

The ignition distributor (fig. 10-16) closes and opens the primary ignition circuit and distributes the high-voltage surge to the proper spark plug at the correct time in the engine cycle. The distributor includes a drive shaft with breaker cam and spark advance mechanism, a breaker plate with contacts, and a rotor. This assembly fits into a cast-iron housing and is usually supported on a bronze bearing. A molded phenol-resin cap, equipped with terminals for the high-tension secondary, is clamped on the top of the housing (fig. 10-16,A).

The shaft with the breaker cam is usually driven by the engine camshaft at one-half the engine speed through spiral gears. The distributor contacts are held closed by spring pressures and opened by the breaker cam, which usually has the same number of lobes as there are cylinders in the engine.

The primary circuit through the ignition distributor includes the distributor contacts and capacitor (fig. 10-16). As the breaker cam rotates, the cam lobes move around under the contact arm, causing the distributor contacts to open and close (fig. 10-16,B). Thus, the distributor contacts open and close once for each cylinder with every rotation of the breaker cam, and one high-voltage surge is produced by the ignition coil for each cylinder with every two revolutions of the crankshaft.

11578

75.185

Figure 10-16.—Ignition distributor.

As mentioned before, the capacitor connected across the distributor contacts provides a quick collapse of the magnetic field in the ignition coil in order to produce the high-voltage surge; it also protects the distributor contacts from arcing.

The secondary circuit through the ignition distributor includes the distributor rotor, distributor cap with high-tension terminals, and the spark plugs (fig. 10-14). The high voltage surge in the ignition coil secondary is conducted through the high-tension lead by way of the center terminal of the distributor cap to the rotor. The rotor is mounted on the breaker cam and rotates with it. During each revolution, a metal spring and segment on the rotor (fig. 10-16,A) connect the center terminal of the distributor cap with each outside terminal in turn. This action directs the high-voltage surges from the ignition coil to the various spark plugs in the engine according to the firing order.

SPARK ADVANCE MECHANISMS

To obtain efficient performance of an internal-combustion gasoline engine for varying conditions of operation, the spark must be timed so that it will occur at the proper time in the compression stroke. For example, when the engine is operating at part throttle, the spark must appear early (before the piston has reached top dead center) to allow sufficient time to ignite the smaller amount of fuel-air mixture (by weight), which is less highly compressed and consequently slower burning. Similarly, when the engine is operating at higher speeds, the spark must appear earlier in the compression stroke in order to give the fuel-air mixture ample time to ignite, burn, and give up its energy to the piston as it starts down on the power stroke. The timing of the spark is usually accomplished by either the centrifugal advance mechanism or the vacuum advance mechanism or both.

Centrifugal Advance Mechanism

The centrifugal advance mechanism is located in the distributor housing below the breaker plate that carries the distributor contacts (fig. 10-17). It consists of an advance cam (which is integral with the breaker cam), two weights, and two weight springs assembled on a weight base that is integral with the distributor shaft (fig. 10-17,A). Each weight is mounted on a stud of the weight base and linked by a weight spring to the advance cam. At low speeds the tension of the weight springs holds the weights in the NO ADVANCE position so that there is no spark advance, and the spark appears in the cylinder just before the piston reaches top dead center on the compression stroke.

11579

77.157
Figure 10-17.—Centrifugal advance mechanism.

As the speed increases, the centrifugal force developed by the rotating shaft tends to move the weights outward against the tension of the springs. The faster the distributor shaft rotates, the greater the centrifugal force, and the greater the movement of the advance weights. The movement of the weights pushes the advance cam and thus the breaker cam ahead (to an advanced position in the direction of rotation) of the distributor shaft (fig. 10-17,B). This action causes the lobes of the breaker cam to open and close the contacts earlier in the compression stroke so that the spark is advanced. The broken line denotes the idle NO ADVANCE position; whereas, the solid line denotes the high-speed FULL ADVANCE position.

The centrifugal advance for any particular engine is determined initially by operating the engine at full throttle on a dynamometer and varying the spark advance at each engine speed until the advance is determined that will provide maximum power at that speed. The centrifugal advance weights, advance cam contours, and weight springs are designed to supply this advance through the speed range of the engine which varies the spark advance at each engine speed until the advance is determined which will provide maximum power at that speed.

Vacuum Advance Mechanism

The vacuum advance mechanism utilizes the vacuum in the intake manifold to provide the additional spark advance required under part-throttle operation (fig. 10-18).

75.187
Figure 10-18.—Vacuum advance mechanism.

The vacuum advance mechanism in which the complete distributor is rotated consists of an airtight, spring-loaded diaphragm that is linked to the ignition distributor (fig. 10-18,A). The spring-loaded side of the diaphragm is airtight and is connected by a tube to the carburetor. This opening is on the atmospheric side of the trottle valve when the throttle is in the idle position so that there is no vacuum advance. However, when the throttle is opened it swings past the opening of the vacuum passage; the intake-manifold vacuum can then act on the diaphragm to compress the spring and rotate the distributor housing in its mounting. This action moves the breaker plate and contacts along with the distributor housing in the direction of rotation of the breaker cam so that

11580

the contacts close and open earlier in the compression stroke to provide the desired vacuum spark advance. The amount of throttle opening determines, in part, the amount of intake manifold vacuum, and thus the amount of spark advance obtained.

The vacuum advance mechanism in which only the breaker plate is rotated (the distributor housing is stationary) has the advance mechanism mounted on the side of the distributor, and the diaphragm is linked to the breaker plate (fig. 10-18,B). The breaker plate is supported on bearings so that it can rotate independently of the distributor housing.

At any particular engine speed there is a definite amount of spark advance, resulting from the operation of the centrifugal advance mechanism due to speed, and an additional amount of advance resulting from the vacuum advance mechanism due to vacuum conditions in the intake manifold.

SPARK PLUGS

The spark plug (fig. 10-19) in a spark ignition system provides the gap across which the high-tension voltage jumps to create a spark that ignites the compressed fuel-air mixture. It consists of a center (insulated) electrode that is connected to the secondary of the ignition coil through the distributor, and a side (grounded) electrode. The center electrode extends through a porcelain insulator that is supported by a circular metal shell. The side electrode protrudes from the edge of the metal shell and is positioned so that a gap exists between it and the center electrode. The base of the shell is threaded to allow it to be screwed into a tapped hole in the cylinder head.

77.158

Figure 10-19.—Spark plug.

The size of the spark-plug gap depends on the engine compression ratio, the characteristics of the combustion chamber, and the ignition system. At one time a gap of 0.025 inch was practically standard on all engines. However, manufacturers now specify gaps of from 0.03 to 0.04 inch to permit more readily igniting the increased mixtures (by weight) used in the higher horsepower engines.

Spark plugs are designed so that the temperature of the firing end is sufficiently high to burn off carbon and other combustion deposits, but not high enough to cause preignition and deterioration of the insulator and electrodes.

The temperature of the insulator depends on the characteristics of the spark plug and on the burning fuel in the combustion chamber. The temperature of the burning fuel in the combustion chamber varies with the engine design, compression ratio, fuel-air ratio, and cooling system. The heat absorbed by the tip of the spark plug from the burning fuel travels up the insulator to the metal shell, to the cylinder head, and to the water jacket. As the temperature in the combustion chamber increases, the heat absorbed by the insulator increases. The tip of the spark plug will have a lower temperature if the length of the path that the heat must travel to reach the cooling system is short as compared to the heat transfer when the path is long. Hence, plugs with short paths are called COLD PLUGS; plugs with long paths are called HOT PLUGS.

Engine manufacturers select plugs that will provide good performance for average operating conditions. However, if the engine is operated for long periods under full-load or overload conditions, the standard-equipment spark plug will operate at too high a temperature and preignition will result. Hence, it will be necessary to install a colder plug to carry off the heat more rapidly. On the other hand, if the engine is operated for long periods at part throttle, the standard-equipment plug may tend to foul due to the accumulation of carbon at

11581

reduced temperature, thereby resulting in poor engine performance. Hence, it will be necessary to install a hotter plug to concentrate the heat and burn off the accumulated products of combustion.

MAINTENANCE

A regular inspection and maintenance procedure is necessary to attain maximum service with minimum trouble. For the ignition distributor, the procedure includes periodic lubrication (where required) and inspection of the breaker contacts, centrifugal and vacuum advance mechanisms, connections, distributor cap, and rotor.

Test the vacuum advance mechanism to be certain it operates freely. On the type that rotates the complete distributor, manually turn the distributor in its mounting and then release it. The vacuum advance spring should return it to its original position without sticking. On the type that rotates the breaker plate only, manually turn the plate. The breaker plate should return to its original position when released.

Test the centrifugal advance mechanism for freedom of movement by turning the breaker cam in the direction of shaft rotation and then releasing it. The advance springs should return the cam to its original position without sticking.

Wipe out the inside of the distributor cap with a clean, lint-free cloth and inspect both the cap and the rotor for chips, cracks, and carbonized paths that would allow leakage of the high-tension voltage to ground. These defects require replacement of the affected part.

After installing new points, test the breaker contact opening with a feeler gage. Do not use the feeler gage to check the opening of old contacts because the contour of these contacts will be irregular, and the gage will measure only the distance between the high spots instead of between the high and low spots, which is the actual opening. To adjust the contact opening, loosen the lock screw and turn the eccentric screw (fig. 10-20). Tighten the lock screw after the adjustment is completed.

The cam (contact) angle is the number of degrees that the breaker cam rotates from the time the contacts close until they again open (fig. 10-20). The cam angle increases as the contact opening is decreased, and conversely, it decreases as the contact opening is increased.

77.159

Figure 10-20.—Distributor adjustments.

Test the breaker contact pressure with a brush tension gage (hooked to the breaker lever and the spring secured to its terminal in the distributor) and exert a pull at an angle of 90° with the contact surface. The reading should be taken just as the contacts separate. Adjust the pressure by bending the breaker lever spring. If the pressure is excessive, it can be decreased by pinching the spring carefully. If the pressure is not sufficient, remove the breaker lever from the distributor and bend the spring away from the lever. It is important to remember that excessive pressure causes rapid wear of the rubbing block, cam, and contacts. Conversely, insufficient pressure permits high-speed bounce of the contacts that causes arcing and burning of the contacts with consequent missing of the engine.

If necessary, clean the contacts with a clean, fine-cut contact file. Remove only the scale or dirt and do not remove all roughness or dress down the contact surfaces. Never use emery cloth or sandpaper because imbedded particles will cause rapid burning of the contacts.

If the contacts burn or pit, they will soon become unsatisfactory for service. They must be replaced and the ignition system and engine must be checked to determine, and eliminate the cause of the trouble. Contact burning will result from high voltage, a defective capacitor, improper contact adjustment, and oil or foreign matter.

High voltage can result from a maladjusted or inoperative voltage regulator, or an excessively advanced third brush on a third-brush generator without a regulator.

Oil or crankcase vapors that work up into the distributor and deposit a film on the contact surfaces will cause them to burn rapidly. This condition can be caused by clogged engine breather pipes, resulting in a crankcase pressure that forces the oil or vapors up into the distributor.

If the contact opening is too small (cam angle too large), the contacts will be closed over a great portion of the total operating time. The current through the contacts will be too high, causing them to burn rapidly and arcing will occur between the contacts, resulting in a low secondary voltage and engine miss.

The capacitor circuit connections should be tested to detect excessive resistance because a high series resistance in the capacitor circuit will prevent normal capacitor action and result in rapid burning of the contacts. This high resistance can be caused by a loose (capacitor) mounting or lead connection. Other capacitor tests should include allowable voltage, insulation resistance, and capacity checks.

Contact pitting will result from an unbalanced condition in the ignition system, causing a transfer of tungsten from one contact to the other to form a tip on one and a pit in the other.

If the tungsten transfers from the negative to the positive contact, one or more of the following corrections may be made: increase the capacity of the capacitor, shorten the capacitor lead, separate the low- and high-tension leads of the distributor-to-coil leads, or move these leads closer to ground (engine block or frame).

If the tungsten transfers from the positive to the negative contact, reduce the capacity of the capacitor, move the distributor-to-coil leads closer together, move these leads away from ground, or lengthen the capacitor lead.

The spark plugs should be removed and inspected for cracked porcelain and wear. If they can be retained in service, file the end of the center electrode to a flat surface, clean both electrodes and then readjust the spark gap in accordance with the manufacturers' specifications. When readjusting the gap, bend the side electrode only. Do not bend the center electrode because it may crack the insulator.

More detailed information concerning the maintenance and repair of the ignition system is contained in the manufacturers' instruction books furnished with the equipment.

AIR HEATERS

Ignition in a diesel engine is accomplished by a combination of fuel injection and compression. Diesel engines normally require a longer cranking period than gasoline engines, and at low ambient temperatures they are more difficult to start because the heat of compression may not be sufficient to ignite the fuel-air mixture. Therefore, at low temperatures it is necessary to preheat the engine by means of an electric air heater, or to furnish an auxiliary low-ignition temperature fuel during the starting period by means of a pressure primer system. The types of air heaters and primers used for starting diesel engines include the (1) grid resistor, (2) glow plug, (3) flame primer, and (4) ether capsule primer.

GRID RESISTOR

The grid resistor usually consists of a 1200-watt resistance grid mounted on a frame and supported by insulating blocks in the engine air-intake manifold. The grid is preheated by current from the starting battery before the engine is cranked and is operated during the cranking period until the engine is running smoothly.

GLOW PLUG

The glow plug consists of a coil of resistance wire enclosed in a stainless-steel tube and is installed in the combustion chamber of each cylinder. The glow plugs are preheated by current from the starting battery and require about the same amount of power and preheat period as the grid resistor.

The glow-plug and grid-resistor type heaters are not used extensively because of the heavy load imposed on the starting battery at the time that the cranking-motor load is heavy.

FLAME PRIMER

The flame primer (fig. 10-21) is the most widely used type of air heater for preheating diesel engines when starting at low temperatures. It is essentially a small, pressure oil burner with electric ignition. The fuel oil is sprayed into the engine air-intake manifold with a manually operated pump, and ignited

11583

75.189

Figure 10-21.—Flame primer.

11283
11584

the rotor is fixed with respect to the aircraft, and the stator is fixed with respect to the gyro, an a-c roll signal is developed when the rotor is displaced by the rolling of the aircraft. When the attitude of the aircraft combines both pitch and roll, pitch and roll signals are simultaneously produced by the gyroscope unit. These signals are fed to the resolver synchro in the antenna assembly. (See fig. 17-37.)

When displacement of the gyroscope synchros occurs, a torque is developed at the stator coils, which, if not compensated for, will cause the gyro to deviate from true vertical, thereby introducing errors into the reflector angle of stabilization. To counteract this effect, a balancing coil connected to a load resistor is mounted along with the stator of each synchro. When displacement of the rotor occurs, the magnetic field developed about the balancing coil causes a torque in the direction opposite to that already exerted on the stator, thus insuring stability of the gyro. The gyroscope unit is mounted on the aircraft structure and is provided with a reference base plate which is adjusted to a plane parallel to that of the antenna platform. The component is also provided with a sighting surface to permit alinement parallel to the lubber line of the aircraft.

Resolver Synchro

Within the resolver synchro, the pitch and roll signals from the gyro are combined by induction in a rotor coil that is geared to the rotary head of the scanner, with which it rotates in a one-to-one ratio. Because of this mechanical coupling, the resultant resolver-synchro signal used in tilt stabilization experiences the proper variation throughout the scanning cycle to maintain the selected reflector tilt angle with respect to the aircraft for every azimuth position of the scanner. The net effect of tilt stabilization is to maintain a fixed predetermined angle of tilt between the reflector and the true horizontal, while the aircraft experiences the usual variations of normal flight.

The pitch and roll signals developed by the gyroscope unit are fed into the separate stator windings of the resolver synchro. These stator windings are mounted at right angles to each other. The orientation of the rotor is adjusted so that when the reflector is dead ahead, pitching of the aircraft causes maximum pitch signal to be induced in the rotor of the resolver synchro; when the reflector is directed to extreme port or starboard, rolling of the aircraft causes maximum roll signal to be induced in the rotor of the resolver synchro. At intermediate positions of the reflector, combinations of both pitch and roll signals are induced in the rotor. One of these voltages may be either aiding or opposing the other, according to the attitude of the aircraft, with respect to the azimuth position of the reflector.

Servoamplifier

The SERVOAMPLIFIER amplifies the error signal resulting from the combining of the manual-tilt synchro signal and the resolver-synchro signal, and controls the voltage to the tilt-torque motor, which corrects the tilt angle of the scanner.

The servoamplifier uses two resistance-coupled amplifiers, followed by a phase-discriminator stage and a pair of d-c amplifiers working into a saturable-reactor assembly. The output of the phase-discriminator stage, amplified by the d-c amplifiers, controls the a-c voltage that drives the tilt-torque motor. The direction of drive, which determines direction of tilt, is governed by the phase relationship between the exciting voltage and the control voltage of this motor; this relationship is, in turn, dependent upon the phase relationship between the motor-exciting voltage and the error voltage at the input of the servoamplifier.

The scanner is maintained at an angle of tilt with respect to the horizon. This angle is determined by the setting of the TILT control. This condition is achieved by combining the signal from the manual-tilt synchro with the one from the resolver synchro at the input of the servoamplifier. (See fig. 17-37.) The signal from the manual-tilt synchro is applied to one side of the ratio potentiometer, R1, and the signal from the resolver synchro is applied, through resistor R2, to the opposite terminal of the same potentiometer, whence they are combined in the servoamplifier. These two signals are 180° out of phase, and when of equal amplitude they cancel each other. When this cancellation is complete, there is no control voltage for the tilt-torque motor, and consequently no tilt action is applied to the scanner.

1156

by means of a spark plug, ignition coil, and vibrator. The device consists of two assemblies. One unit contains the burner, ignition coil, and vibrator. The other unit comprises the pressure pump and ignition switch. The principal advantage of the flame primer is that it imposes a negligible load on the starting battery.

The heater unit consists of a nozzle, filter, ignition electrodes, and ignition coil with vibrator. One side of the heater body contains the filter, nozzle, and ignition electrodes and the other side contains the ignition coil, terminals, and connection for the fuel supply. The unit is designed to replace one of the hand-hole cover plates nearest the center of the engine air box. The entire heater unit is provided with a protective metal cover. The air necessary for combustion is obtained from the charging blower, and the products of combustion including the flame-heated air are discharged into the engine cylinders (with practically no heat loss), resulting in an immediate response of the engine.

The pressure pump and ignition switch (fig. 10-21) are mounted on the instrument panel near the engine starter switch so that both the ignition switch and engine starter switch can be depressed simultaneously with one hand, thereby leaving the other hand free to operate the pump. The pump supplies fuel under pressure to the heater unit where the charge is filtered before reaching the nozzle. The suction side of the pump is either connected directly to the main fuel tank, or to the engine supply line between the main tank and the engine transfer pump. When the pump plunger is not in use, it is held in the IN position by a spring mechanism. The pump plunger is designed so that a pressure of about 10 pounds on the knob will deliver (from the nozzle) a finely atomized fuel. This fuel is readily ignited by the sparks at the electrodes in the heater unit. The rate of travel of the plunger on the pumping stroke is determined by the flow of oil from the discharge nozzle, and normally requires 3 or 4 seconds per stroke.

The ignition switch is connected in the line between the starting battery and one terminal of the ignition coil in the heater unit. The other terminal (primary) of the ignition coil is grounded to the engine.

If the engine fails to fire after two or three strokes of the primer pump while cranking the engine with the throttle wide open, stop cranking and examine the flame primer for possible causes of failure. If the engine is operating satisfactorily and the cranking speed is 80 rpm or more, test the flame primer for (1) ignition failure and (2) poor oil spray. If possible, remove the burner element from the engine so that the burner operation can be readily observed.

To test the flame primer for IGNITION FAILURE, depress the ignition switch to the ON position and observe the action of the ignition-coil interrupter inside the coil assembly. It should vibrate rapidly and a continuous hot spark should occur between the ignition electrodes. If the interrupter does not vibrate, examine the interrupter contacts for dirt or carbon. Also examine the wiring for loose or broken connections. Clean the contacts with fine sandpaper and reset the air gap to one-eighth inch with the vibrator armature held against the coil.

If the spark jumps across the porcelain of the electrode, check the gap and reset it to about one-eighth inch (if necessary) by loosening the set screw and moving the grounded electrode. If the air gap is correct, remove the threaded gland on the porcelain electrode and withdraw the electrode assembly. Wash the porcelain with a cleaning solvent and scrape off any accumulation of carbon. Reassemble the porcelain electrode after it has been cleaned properly.

ETHER CAPSULE PRIMER

The ether capsule primer (fig. 10-22) consists of a (1) discharger cell, (2) discharger nozzle, and (3) pressure primer bulb that contains a liquid ether mixture. The discharger cell and the discharger nozzle are connected together by a suitable length of 3/16" tubing. The discharger cell is a metal enclosure containing a piercing pin and provided with a removable cap for inserting the pressure primer (capsule) bulb. The cap is equipped with a discharger lever. When this lever is operated, it forces the capsule bulb against the piercing pin.

The discharger cell is installed at the control station in a vertical position so that the neck of the capsule bulb is always down toward the piercing pin. The discharger nozzle is installed through a 1/4" pipe connection at the forward end of the intake manifold.

When the ether capsule primer is used for cold-weather starting, press the engine starter

11585
DECL

a time, and at about two-minute intervals to allow the heat to dissipate. The starting current on most small boats is over 600 amperes.

The starting motor is equipped with a drive mechanism that transmits the power from the motor to the engine. The function of the drive mechanism is to (1) engage the drive pinion with the flywheel for cranking the engine, (2) provide a gear reduction between the drive pinion and flywheel, and (3) disengage the drive pinion and flywheel after the engine is started.

When the starting motor is operated, the drive mechanism causes the drive pinion to mesh with the teeth of the flywheel ring gear, thereby cranking the engine.

The gear reduction is necessary because the starting motor must rotate at a relatively high speed with respect to the engine cranking speed to produce sufficient output power to crank the engine. Thus, a gear reduction ratio of 15 to 1 will permit the starting motor to rotate at 1500 rpm while cranking the engine at 100 rpm.

As soon as the engine is started, the drive mechanism causes the drive pinion to disengage from the flywheel. The engine speed increases immediately and may soon attain speeds up to 1000 rpm. If the drive pinion is allowed to remain in mesh with the flywheel, the engine would drive the starting motor at speeds up to 15,000 rpm, resulting in serious damage to the motor.

The types of drive mechanisms provided on starting motors are the (1) Bendix drive, (2) overrunning clutch drive, and (3) Dyer drive.

BENDIX DRIVE

The Bendix drive provides an automatic means of engaging the drive pinion of the starting motor with the engine flywheel ring gear for cranking the engine and for disengaging the drive pinion from the flywheel after the engine starts. This drive mechanism (fig. 10-23) consist of a drive pinion mounted on a threaded sleeve, or hollow shaft, which has spiral threads that match the internal threads in the drive pinion. The sleeve fits loosely on the armature shaft of the starting motor. One end of the sleeve is bolted to the drive spring. The other end of the drive spring is keyed and bolted to the armature shaft through the drive head.

When the starting motor is not in operation, the pinion is disengaged from the flywheel ring gear. As soon as the starting switch is closed, the armature begins to rotate and its speed increases very rapidly. The threaded sleeve picks up speed with the armature as it is

75.172

Figure 10-23.—Bendix drive.

884587

driven through the drive spring. The drive pinion does not pick up speed instantly because it fits loosely on the sleeve. Hence, the sleeve turns within the drive pinion, forcing the pinion along the shaft and into engagement with the flywheel ring gear. As the drive pinion reaches the stop on the end of the sleeve, it then rotates with the sleeve and the armature so that the engine is cranked.

The drive spring compresses slightly to absorb the shock when the gears are meshed to prevent the shock from being transmitted back through the starting motor. Bendix heavy-duty drives are provided with a friction clutch interposed between the drive spring and drive pinion. The clutch comprises a series of spring-loaded clutch plates that slip momentarily during engagement to absorb the shock.

After the engine starts, the flywheel drives the pinion at a higher speed than the speed at which the armature and the threaded sleeve are revolving. This action causes the pinion to be turned relative to the threaded sleeve and in such a direction that the pinion is backed out of engagement with the flywheel ring gear.

Some Bendix drives are provided with a small antidrift spring between the drive pinion and the pinion stop. This device prevents the pinion from drifting into mesh when the engine is running. Other Bendix drives use a small antidrift pin and spring inside the pinion. This device provides sufficient friction to keep the pinion from drifting into mesh.

OVERRUNING CLUTCH DRIVE

The overrunning clutch drive provides positive engaging and disengaging of the starting-motor drive pinion and the flywheel ring gear. This drive mechanism (fig. 10-24) utilizes a shift level that slides the clutch and drive pinion assembly along the armature shaft so that it can be engaged and disengaged with the flywheel ring gear. The clutch transmits cranking torque from the starting motor to the engine flywheel, but permits the pinion to overrun the armature after the engine starts. Thus, power can be transmitted through the overrunning clutch in only one direction. This action protects the starting motor from excessive speed during the brief interval that the drive pinion remains engaged with the flywheel ring gear after the engine has started.

The overrunning clutch consists of a shell-and-sleeve assembly (fig. 10-24) that is splined internally to match the splines on the armature shaft. Thus, both the shell-and-sleeve assembly and the armature shaft must turn together. A pinion-and-collar assembly fits loosely into the shell. The collar is in contact with four steel rollers that are assembled into notches cut in the inner face of the shell. The notches taper inward slightly so that less space is in the end away from the rollers. The rollers are spring loaded by means of springs and plungers.

When the shift lever is operated, the clutch assembly is moved along the armature shaft until the pinion engages with the flywheel ring gear. If the teeth should butt instead of engage, the clutch spring compresses so that the pinion is spring loaded against the teeth of the ring gear. Thus, engagement of the teeth takes place immediately when the armature begins to rotate.

The starting-motor switch is closed when the movement of the shift lever is completed, causing the armature to rotate. This action rotates the shell-and-sleeve assembly, causing the rollers to move forward (in the direction of rotation) and jam tightly in the smaller sections of the notches. The rollers jam between the pinion collar and the shell so that the pinion is forced to rotate with the armature, and thereby crank the engine.

After the engine starts, it spins the pinion faster than the armature of the starting motor is rotating. This action causes the pinion to rotate with respect to the shell so that it overruns the shell and starting-motor armature. The rollers are now rotated backward into the larger sections of the notches where they are free, and thus they permit the pinion to spin independently of, or overrun, the shell and sleeve assembly. This feature protects the armature for the brief interval after the engine starts until the operator releases the starting-motor switch. When the starting-motor switch is opened, the shift lever releases, causing the drive spring to pull the overrunning clutch drive pinion out of engagement with the engine flywheel ring gear.

DYER DRIVE

The Dyer drive provides for positive engagement of the starting-motor drive pinion with the engine flywheel ring gear before the starting-motor switch is closed. It is used for heavy duty applications where it is important to avoid clashing of gears because of the relatively high horsepower developed in cranking these

V8 11588

Figure 10-24.—Overrunning clutch drive with solenoid-operated switch. 75.173

11589
00211200

engines. As soon as the engine starts, the flywheel spins the drive pinion more rapidly than the armature and shaft assembly are turning. This action backs the pinion out of mesh with the flywheel ring gear so that the armature of the starting motor is not subjected to excessive speeds.

This drive mechanism (fig. 10-25) consists of a shift lever, a shift sleeve, a pinion guide, a pinion spring, a pinion, a pinion stop, and thrust washers. The pinion guide fits snugly on the spiral splines of the armature shaft, and the pinion (which has internal splines that match the armature splines) fits loosely on the splines of the armature shaft. When the drive assembly is at rest, the drive pinion is retained in the disengaged position by the pinion guide, which drops into milled notches in the armature splines. The pinion can be released from this position only by movement of the pinion guide through operation of the shift lever.

When the shift lever is operated, the movement causes the shift sleeve, pinion guide, pinion spring, and pinion to be moved along the armature shaft so that the pinion engages with the flywheel ring gear if the teeth are aligned properly. Further movement of the shift lever closes the starting-motor switch, causing the armature to rotate, and thereby crank the engine. If the teeth are not aligned and engagement cannot take place at once, the pinion is rotated against the ring gear teeth until the teeth align and engagement is accomplished.

The pinion rotates because the pinion fits loosely on the armature-shaft splines, and the pinion guide fits tightly on the spiral splines of the armature shaft. The continued forward movement of the pinion guide causes it to

75.174

Figure 10-25.—Dyer drive.

11590

rotate as it follows the spiral splines on the armature shaft. This rotation is transmitted by means of the two lugs on the pinion guide to the pinion. The pinion rotates without any forward movement until alignment of the teeth takes place, then the pinion is thrust forward into engagement with the flywheel ring gear.

The pinion stop limits the forward movement of the pinion. As the shift lever completes its travel, it closes the starting-motor switch, which is linked mechanically with the shift lever, and the armature of the starting motor begins to rotate. As soon as the armature of the starting motor begins to rotate, the friction of the armature shaft in the shift sleeve causes the shift sleeve to rotate. The stud on the end of the shift lever is in the slot in the shift sleeve so that rotation of the shift sleeve causes it to move back out of the way from the drive pinion. Cranking takes place as the shaft splines cause the drive pinion to rotate with the armature shaft.

As soon as the engine begins to operate, it spins the drive pinion faster than the armature is rotating, causing the drive pinion to be spun back out of engagement with the flywheel ring gear. As the pinion moves back out of engagement, the pinon guide drops into the milled section of the shaft splines to lock the pinion in the disengaged position. It is impossible to start another cranking cycle without completely releasing the shift lever. The shift lever must drop back to the disengaged position so that the stud can rotate the shift sleeve and reengage the flat section of the spiral slot in the shift sleeve. Movement of the shift sleeve will then cause the cranking cycle to again take place.

The drive pinion will not engage with the flywheel ring gear while the engine is operating because when the pinion teeth touch the teeth of the moving flywheel ring gear, the shift sleeve will be rotated, and the pinion will follow the splines on the armature shaft back to the located position.

CONTROLS

The controls used with starting motors in small craft are the (1) magnetic switch and (2) solenoid switch.

The magnetic switch (fig. 10-26) is used to close the motor switch on some starting motors equipped with Bendix drive. It is usually mounted on the motor frame and consists of a coil provided with a spring-loaded plunger. The coil is connected in series with a starter switch located on the instrument panel. When the starter switch is operated, the coil is energized from the battery and pulls the plunger so that the contact disk is forced across two contacts to complete the circuit between the battery and the starting motor.

77.160

Figure 10-26.—Magnetic switch.

The solenoid switch (fig. 10-27) is used on some starting motors equipped with overrunning clutch drives and Dyer drives to close the circuit to the starting motor and also to engage the pinion with the flywheel ring gear. It is mounted on the motor frame and consists of a pull-in coil and a hold-in coil provided with a spring-loaded plunger. A heavy contact disk is attached to one end of the plunger, and the other end is connected by linkage to the shift lever. Both coils are connected in series with a starter switch located on the instrument panel. When the starter switch is operated, both coils are energized (from the battery) and the plunger is pulled so that the pinion engages with the flywheel ring gear. The pull-in coil draws a comparatively heavy current necessary to complete the plunger movement. The hold-in coil aids the pull-in coil. Continuation of the plunger movement closes the switch contacts, thereby permitting the starter motor to crank the engine. As soon as the solenoid switch is closed (and

11591

Figure 10-27.—Solenoid switch.

the pinion shifted), the pull-in coil is shorted by the switch contacts in the starting-motor circuit so that only the hold-in coil is energized to retain the plunger in the operated position.

When the starter switch is released, the tension of the return spring in the drive assembly actuates the plunger to open the circuit to the starting motor.

MAINTENANCE

A regular inspection and maintenance procedure should be followed to obtain the maximum service with minimum trouble from starting motors in small craft. Periodic inspections of the brushes, commutator, drive assembly, and lubrication (where required) are essential. Also, disassembly and thorough overhauling of the starting motor at periodic intervals are necessary to ensure against failures caused by accumulations of grease and moisture and normal wear of the parts. The external circuit between the starting motor and the battery, including the magnetic switch or solenoid switch, must be properly maintained because defective wiring, such as loose or corroded connections, will prevent normal performance of the starting system.

The following intervals of inspection are based on average operating conditions but can be adapted for specialized operations.

EACH WEEK, visually check the connections and cables between the starting motor and the battery. Also, check the mounting bolts to be certain they are secure.

EACH MONTH, lubricate the starting motor by adding a few drops of light engine oil to the hinge-cap oiler. On motors equipped with grease cups, turn the grease cups down one turn. Be certain that the cups are filled with medium cup grease. Remove the cover band and inspect the commutator and brushes. If the commutator is dirty, clean it with a strip of No. 00 sandpaper held against it with a piece of soft wood while operating the starting motor with the ignition switch in the OFF position. Blow out the dust with compressed air or a bellows. If the commutator is rough, out-of-round, or has high mica, turn it down in a lathe in accordance with the procedures described in chapter 6 of this training course.

EACH YEAR, remove and disassemble the starting motor so that all parts can be cleaned and the worn parts replaced. Check the brush holders to be certain they are free on their pivots and have the correct spring tension. Clean the bearings and repack them with the proper grease. On motors equipped with oil wicks, saturate the wicks with oil before reassembly. On motors equipped with oil-less type bushings, supply a few drops of light engine oil on the bushings at any time the starting motor is disassembled for repair or service. Avoid excessive lubrication.

The Bendix drive should be washed in kerosene and then lubricated by applying a small amount of light engine oil. Do not over oil this mechanism because it might cause the pinion to stick. Replace the pinion if the pinion teeth are burred. Inspect the drift-pin spring because, if the spring is weak, the pinion might tend to drift into engagement with the flywheel ring gear while the engine is running.

The overrunning clutch drive is packed with a special high melting-point grease when the clutch is initially assembled and requires no further lubrication. Do not clean the clutch by grease-dissolving or high-temperature methods because this would cause the clutch to lose its lubricant. Replace the clutch if the pinion does not turn freely in the overrunning direction, if the pinion tends to slip in the cranking direction, or if the pinion is excessively loose. When the overrunning clutch is operated by means of a solenoid switch, check the clearance (fig. 10-24) between the pinion and the bearing housing

11592

when the pinion is in the operated position. This clearance should be three-sixteenths inch and is adjusted by turning the stud in the solenoid plunger in or out as required.

The Dyer drive should be lubricated with a small amount of light engine oil after reassembly. Do not use heavy oil or grease as it might retard or prevent normal drive performance. The adjustment of the drive mechanism must be checked to be certain that the travel of the pinion against the pinion spring is correct when the pinion is in the cranking position. When the shift lever is in the cranking position, it should be possible to push the pinion one-eighth to three-sixteenths inch back against the pinion spring pressure (fig. 10-25). This free travel adjustment can be checked on the solenoid-operated starting motor by disconnecting the lead between the solenoid and starting motor and connecting a battery of the specified voltage to the two terminals on the solenoid.

Manually operate the shift lever until the switch is closed. The current from the battery will maintain the switch in the operating position so that the pinion travel can be checked. The travel is adjusted by turning the stud in the solenoid plunger in or out as required. More detailed information concerning the adjustments, tests, and maintenance of starting motors is contained in the manufacturers' instruction books furnished with the equipment.

LIGHTING SYSTEM

The lighting system in small craft includes the (1) compartment lighting, (2) hand lanterns, (3) portable multipurpose signaling light, and (4) navigational lights.

GENERAL LIGHTING

The general lighting includes the compartment lighting and hand lanterns.

Compartment Lighting

The compartment lighting for general illumination consists of units similar to that shown in figure 10-28. This fixture is non-adjustable and consists of a steel enclosure and a bowl-shaped globe. The lampholder is equipped with a bayonet candelabra double-contact base.

77.162

Figure 10-28.—Compartment lighting fixture.

Hand Lantern

The hand lantern for general use is a manually operated type identical to those described in chapter 4 of this training course.

SIGNALING LIGHT

The portable multipurpose signaling light is similar to that shown in figure 10-29. It consists of a metal housing provided with a black phenolic, louvered signaling tube and a metal pistol-grip handle with trigger switch for blinker communications. A spotlight that has a 5-inch diameter parabolic-type reflector with a clear glass lens and a rheostat, for varying the light intensity, are mounted inside the metal housing. The light uses a candelabra, single-contact lamp with bayonet-type prefocusing base. A 25-foot cable with plug is connected to the light through the bottom of the handle for the power supply and remote signaling key. The power supply consists of a transformer and provision for a type BA-207/U battery mounted in a carrying kit. The remote signaling key is equipped with a cable and plug.

Also included with the multipurpose light are a buzzer for an audible signal, a short signal

11593

77.163
Figure 10-29.—Multipurpose signaling light.

tube, a long signal tube, an open-type sight, and a spare parts box with two lamps and a remote signaling key.

NAVIGATION LIGHTS

The International Conference of Safety of Life at Sea made changes to the International Regulations which affect small boats. The new Regulations classify boats according to length rather than tonnage. The EM should ensure that lights are working and that they are not relocated to such a position that they do no conform to the requirements of the Regulations. The following summarizes the general requirements for the lights:

ANCHOR LIGHT: In the fore part of all boats, there should be mounted where it can best be seen, a 32-point white light visible all round the horizon at a distance of at least two miles.

MASTHEAD LIGHT: In the fore part of boats 65 feet and over in length, provide a 20-point white light to show an unbroken light over an arc of the horizon of 10 points on each side of the boat from right ahead to 2 points abaft the beam on either side and visible at a distance of at least 5 miles. Locate light at a height not less than 20 feet above the hull or if breadth of the boat exceeds 20 feet, then a height above the hull not less than such breadth.

In the fore part of boats 40 feet to 65 feet in length, provide a 20-point white light to show an unbroken light over an arc of the horizon of 10 points on each side of the boat from right ahead to 2 points abaft the beam on either side and visible at a distance of at least three miles. Locate light at a height not less than 9 feet above the gunwale and at least 3 feet above the side lights.

For boats under 40 feet in length, provide a 20-point white light to show an unbroken light over an arc of the horizon of 10 points on each side of the boat from right ahead to 2 points abaft the beam on either side. Locate light at least 3 feet higher than the side lights.

COMBINATION ANCHOR LIGHT AND MASTHEAD LIGHT: On boats less than 65 feet in length, the Masthead Light and the Anchor Light may be combined in a single combination light.

SIDE LIGHTS: For boats 65 feet and over in length, starboard side light and port side light should be located so as not to be obstructed by deck fittings or to be interfered with by personnel. These are each 10-point lights mounted to show an unbroken light over an arc of the horizon from right ahead to 2 points abaft the beam and visible at a distance of at least 2 miles. The Regulations required that on boats over 65 feet in length, the side lights shall be provided with inboard screens at least 3 feet forward from the light so as to prevent the lights from being seen across the bow. On boats which have the lights mounted on the pilot house, the pilot house can serve as the screen to prevent the lights being seen across the bow.

For boats less than 65 feet in length, the starboard side light and port side light should be located so as not to be obstructed by deck fittings or to be interfered with by personnel. These are each 10-point lights mounted to show an unbroken light over an arc of the horizon from right ahead to 2 points abaft the beam and visible at a distance of at least 1 mile. A combined green and red lantern may be used and, if used, should be carried not less than 3 feet below the 20-point white light.

STERN LIGHT: On the stern of all boats, a white light should be located so as to show an unbroken light over an arc of the horizon of 12 points, so fixed as to show the light 6 points from right aft on each side of the boat and visible at a distance of at least two miles.

In a small boat, if it is not possible on account of bad weather or other sufficient cause

11293 11594

When the aircraft rolls, the resolver-synchro signal is altered in amplitude, provided the scanner is not directed dead ahead or aft (at 0° or 180° azimuth). When the aircraft pitches, the resolver-synchro signal is altered in amplitude, provided the scanner is not directed at 90° or 270° relative azimuth. As a result, the resolver-synchro signal and the manual-tilt-synchro signal no longer cancel, and an error signal is developed at the input of the servoamplifier. After amplification, this error signal is applied to a phase discriminator, which determines from the phase of the signal whether the reflector must be tilted up or down in order to correct for the roll, pitch, or combination of the two that has just caused the error signal. The output of the phase discriminator drives the proper tilt-servocontrol tube, which then applies the control voltage to the tilt-torque motor by means of a saturable reactor. As the tilt-torque motor corrects the scanner tilt angle, the rotor of the followup synchro, which is coupled to the tilt-torque motor, is turned in such a direction that the manual-tilt synchro signal changes in amplitude to compensate for the change in the resolver-synchro signal. When these two signals cancel again, the necessary correction to the reflector tilt angle has been accomplished, and the tilt-torque motor stops.

The ratio potentiometer, R1, balances the signals from the manual-tilt synchro and the resolver synchro to compensate for possible deviation from the true horizontal of the mounting plane of the gyroscope unit.

This servoamplifier functions similarly to the one discussed under "Azimuth Stabilization" in this chapter, in that the error voltage controls the saturable reactor which provides the variable voltage for the control winding of the tilt-torque motor. (See fig. 17-37.)

In this tilt stabilization system one winding of the TILT-TORQUE MOTOR is continuously excited by 115 volts a.c. The other winding, used to control the starting and operation of the motor, is supplied from the saturable reactors with a-c voltage developed whenever an error signal is amplified by the servoamplifier. The motor torque is obtained by providing approximately 90° phase difference between the control voltage and the excitation voltage, by means of capacitor C10 which is shunted across the control winding. The speed of the motor is dependent upon the amplitude of the control voltage, which in turn is dependent upon the action of the TILT control, tilt stabilization, and damping.

Manual-Tilt Control

The scanner tilt angle is controlled by the tilt synchro in the radar set control and is adjusted by means of the TILT control. The tilt synchro is connected with the followup synchro in the tilt-servo unit. Supplied with a steady a-c voltage, this synchro circuit develops the manual-tilt synchro signal in its rotor to control the tilt angle of the beam with respect to the angle of tilt stabilization (approximate horizon). The signal from the manual-tilt synchro is fed to the input of the servoamplifier, where it is combined with the resolver-synchro signal. Control of the scanner tilt angle is therefore dependent upon the resultant sum of these two voltages, and is accomplished through the system used for tilt stabilization, as just described. If the resolver-synchro signal is switched off by means of the STAB-UNSTAB switch S2 on the servoamplifier, the beam-tilt angle is then established only with respect to the aircraft.

Followup Synchro

The followup synchro and the manual-tilt synchro develop the manual-tilt synchro signal. The followup synchro is located in the tilt-servo unit of the antenna assembly. The rotor of this synchro is mechanically coupled to the tilt mechanism so that the rotor movement occurs in synchronism with the tilting of the scanner. The stator windings of the followup synchro are connected to the stator windings of the manual-tilt synchro in the radar control unit. The rotor of the followup synchro is supplied with 26-volt, 400-cycle, single-phase voltage. Voltages of unequal amplitude are induced in the stator windings (fig. 17-37). These voltages are reproduced in the stator windings of the manual-tilt synchro in the radar set control. When the rotor position of the manual-tilt synchro is such that its signal cancels the resolver-synchro signal and produces a null at the input of the servoamplifier, no control voltage is developed for the tilt-torque motor and the scanner tilt angle is not changed. When the rotor is displaced from this position in either direction by resetting

1157
1128

for this light to be fixed, an electric torch or lighted lantern showing a white light shall be kept at hand ready for use and shall, on the approach of an overtaking vessel, be shown in sufficient time to prevent collision.

TOWING LIGHTS: A boat 65 feet and over in length when towing or pushing another vessel or seaplane shall, in addition to her side lights, carry two white lights in a vertical line one over the other, not less than 6 feet apart, and when towing and the length of the tow exceeds 600 feet, shall carry three white lights in a vertical line one over the other, so that the upper and lower lights shall be the same distance from, and not less than 6 feet above or below, the middle light. Each of these lights shall be of the same construction and character and one of them shall be carried in the same position as the 20-point white light.

For boats less than 65 feet in length, the above requirements apply except that the vertical spacing between lights shall be not less than 4 feet in lieu of 6 feet.

TASK LIGHTS: For any boat engaged in laying or in picking up a submarine cable or navigation mark, or a boat engaged in surveying or underwater operations, or when from the nature of her work she is unable to get out of the way of approaching vessels, shall carry, in lieu of the Masthead Light, three lights in a vertical line one over the other stepped out 45 degrees aft and to starboard of the mast so that the upper and lower lights shall be the same distance from, and not less than 6 feet above or below, the middle light. The highest and lowest of these lights shall be red, and the middle light shall be white, and they shall be of such a character as to be visible all around the horizon at a distance of at least 2 miles.

CONTROLS: Switches and dimmers are provided, as required, for control of the Navigation Lights.

FIXTURES: Standard fixtures for small boats furnished in accordance with Military Standard MS 17847 (SHIPS) "Lights, Navigational, for Small Boats" are suitable for the required areas of visibilities indicated above. However, the fixtures must also be equipped with lamps of the proper candle power or watt rating to ensure compliance with the distance requirements.

SPOTLIGHT - FLOODLIGHT

Spotlights and floodlights installed in small boats for navigational purposes consist of a spraytight, chromium-plated copper housing equipped with a 100-watt, 7-inch diameter sealed-beam lamp. These spotlights or floodlights are standard Navy type for deck mounting and are controlled locally at the light, or provided for mounting on top of a canopy and controlled from beneath the mounting surface. The type of sealed beam lamp installed in the housing determines whether a spotlight or a floodlight is produced.

SEARCHLIGHT

The 8-inch sealed-beam signal searchlight is also available for use on small craft, as discussed in chapter 5 of this training course.

TRANSISTOR IGNITION SYSTEMS

The transistor ignition system is a relatively new development. The output of the conventional ignition system is limited to the amount of current in the primary circuit. Approximately 5 amperes can be carried in the primary circuit and still maintain a reasonable distributor contact point life. This is because the contact points will arc and burn if more current is interrupted. Because the transistor ignition system has not been widely used in the Navy, only a brief discussion is given in this chapter. In the future the shipboard electrician will see more and more equipment such as voltage regulators and motor controllers using transistors and other solid-state devices. It is therefore recommended that you read chapter 5 of Introduction to Electronics, NavPers 10084, and chapter 2 of Basic Electronics, NavPers 10087-A. These publications give good coverage of transistors. Figure 10-30 is a typical contact controlled transistor ignition system. The only differences between this and a conventional ignition system are the transistor amplifier, a special ignition coil, and the two resistors R3 and R4. The conventional distributor is used without any modification. Basically this system operates in the following manner.

When the ignition switch (fig. 10-30) is turned to the start position (assume the distributor contacts are closed) it bypasses resistor R-3 (to give maximum voltage during cranking) and current enters the amplifier and flows through the resistor R-2, the transistor TR-1, the resistor R-1, the distributor contact points and to ground, the primary of the ignition coil and

11595

Figure 10-30.—A typical contact controlled transistor ignition system. 77.251

resistor R-4 to ground. As soon as the engine turns over and the distributor points open, interrupting the flow of current through the emitter-base of the transistor (marked E and B in figure 10-30), the transistor immediately "shuts off" the emitter-collector current (marked E and C). The flow of electrons in this system is indicated by the solid and dashed arrows on figure 10-30. The dashed arrow indicates the flow of the control (bias) current, the solid arrow the collector current. When the transistor is forward biased, as this one is when the distributor points are closed (the base is negative and the emitter is positive), the electrons flow as indicated by the arrows. When the distributor points are open, the base becomes positive and electron flow stops. When the emitter-collector current stops, the collapsing field of the primary of the ignition coil induces a high voltage in the secondary of the coil and this high voltage is fed via the distributor rotor to the proper spark plug. This procedure is repeated each time the distributor control points open and close. In this system the distributor contact points are carrying only a very small current to control the transistor (turn it on the off), thus contact life is greatly increased. At the same time the ignition coil is carrying a high primary current than is possible on a conventional system, thus a higher secondary voltage output and a better spark for improved ignition.

There are several kinds of transistor ignition systems. They may vary in design but their operating principles are similar. The main difference is that in some systems the transistor is triggered by a magnetic pulse

11596

generator in a special distributor instead of by contact points.

If you ever need to make repairs to a transistor ignition system, consult the manufacturer's manual and trouble-shooting chart. In these systems, one flash of current in a reverse polarity may damage some parts of the system beyond repair.

11597

CHAPTER 11

POWER DISTRIBUTION

Electrical power is indispensable to the operation of modern naval ships. With hydraulic systems it trains and elevates gun mounts and missile launchers, turns the rudder, and runs numerous auxiliaries. It furnishes light and power for running the ship. It operates the interior-communication, fire control, radar, radio, and sonar systems. The power is supplied by electric generating plants that may be either alternating-current or direct-current systems. A-c systems are installed in new construction carriers, cruisers, submarines, destroyers, escort ships, and numerous auxiliary ships. D-c systems are installed on new construction submarines, small surface ships, and large auxiliary ships with considerable deck machinery that requires d-c service for its operation. D-c systems are used in numerous ships converted for Navy use, and on other ships built prior to adoption of a-c ship service systems. Many of the older converted (merchant marine type) ships with d-c power distribution systems are still in the fleet. The amphibious forces have the largest number of these older converted types.

A-C ELECTRIC POWER SYSTEMS

A typical a-c power system consists of the ship service power, the emergency power, and the casualty power systems. (The coverage of casualty power systems in this chapter will be applicable to both a-c and d-c systems.)

D-c power in ships with a-c power systems is furnished either by over-size exciters for the ship service generators, by motor-generator sets or rectifier power supplies. The principal d-c loads are degaussing systems, carbon-arc searchlights, battery charging stations, and the interior-communication and fire control systems.

ELECTRIC PLANT

The ship's overall electric plant consists of the equipments installed for producing electrical power.

The electric plant includes the ship service electric plant and the emergency electric plant.

Ship Service Electric Plant

The ship service electric plant comprises the ship service generator sets, which are driven by steam turbines, diesel engines, or gas turbines. These generator sets supply power to the ship service power distribution system, which is the normal source of power to the ship's electrical equipment and machinery.

The number, type, and capacity of the ship service generators are determined by the load imposed on the generating plant by all of the connected auxiliaries under the various conditions of peacetime or wartime operations.

Emergency Electric Plant

The emergency electric plant comprises the emergency generator sets, which are driven by diesel engines or gas turbines. If power is not available from the ship service generators, the emergency generators supply a limited amount of power to vital auxiliaries through the emergency power distribution system.

The number and rating of the emergency generators must be sufficient to carry the loads that are designated to receive emergency power, but not to supply all of these loads simultaneously. The emergency generator capacity is determined by a particular combination of these loads, the choice of which depends on the type of ship. The ship service generators are required to operate in parallel; whereas, the emergency generators are not normally operated in parallel with each other or with the ship service

11598

generators. However, on some new construction the emergency generator is also used as a standby ship service generator. The electric plant is ungrounded except as required for ground detectors, instrument grounds, equipment frame grounds, personnel protection, or other special grounding requirements.

POWER DISTRIBUTION SYSTEMS

The power distribution systems are the connecting links between the generators that supply electric power and the electrical equipment that utilizes this power to furnish the various services necessary to operate the ship. The power distribution system comprises the (1) ship service power distribution system, (2) emergency power distribution system, and (3) casualty power distribution system.

The majority of a-c power distribution systems in naval ships are 450-volt, 3-phase, 60-cycle, 3-wire systems. The lighting distribution systems are 120-volt, 3-phase, 60-cycle, 3-wire systems supplied from the power circuits through transformer banks.

Ship Service Power Distribution System

The ship service power distribution system is the electrical system that normally supplies electric power to the ship's equipment and machinery. The switchboards and associated generators are located in separate engineering (on combatant ships) spaces to minimize the possibility that a single hit will damage more than one switchboard.

The ship service generator and distribution switchboards are interconnected by bus ties so that any switchboard can be connected to feed power from its generators to one or more of the other switchboards. The bus ties also connect two or more switchboards so that the generator plants can be operated in parallel. In large installations (fig. 11-1) distribution to loads is from the generator and distribution switchboards or switchgear groups to load centers, to distribution panels, and to the loads, or directly from the load centers to some loads.

On some ships, such as large aircraft carriers, a system of zone control of the ship service and emergency distribution is provided. Essentially, the system establishes a number of vertical zones, each of which contains one or more load center switchboards supplied through bus feeders from the ship service switchgear group. A load center switchboard supplies power to the electrical loads within the electrical zone in which it is located. Thus, zone control is provided for all power within the electrical zone. The emergency switchboards may supply more than one zone, the number of zones depends on the number of emergency generators installed.

In small installations (fig. 11-2), the distribution panels are fed directly from the generator and distribution switchboards. The distribution panels and load centers (if any) are located centrally with respect to the loads that they feed. This arrangement simplifies the installation and requires less weight, space, and equipment than if each load were connected to a switchboard.

POWER CIRCUITS.—The designations and terms for most circuits have changed in recent years. The terms "general power" and "battle power" are no longer used but their circuit designations may still be found on older ships where the tags on cables, and identification plates on panels, controllers, circuit breakers, etc., have not been changed.

The following is a listing of the old and new circuit designations.

Circuit designations (old):

- C—Interior Communication
- D—Degaussing
- F—Ship service lighting and general power
- FB—Battle power
- G—Fire control
- MS—Minesweeping
- P—Electric propulsion
- R—Radio and Radar
- RL—Running, anchor and signal lights
- S—Sonar
- XFE—Emergency lighting and power

Circuit designations (new):

- C—Interior Communication
- D—Degaussing
- EL—Lighting emergency
- EP—Power emergency
- FL—Night fluid lights
- G—Fire control
- K—Power control
- L—Lighting ship service
- LP—Power casualty
- MS—Minesweeping
- N—Lighting, navigational
- P—Power, ship service
- PP—Power propulsion

Figure 11-2.—Power distribution in a destroyer.

11601 11603

R—Electronics
SF—Power, special frequency

At least two independent sources of power are provided for selected vital loads. The distribution of this dual supply is accomplished in several ways: by a normal and an alternate ship service feeder; normal ship service feeder and an emergency feeder; or normal and alternate ship service feeder and an emergency feeder.

BUS TRANSFER EQUIPMENT.—Bus transfer equipment is installed at load centers, distribution panels, or loads that are fed by both normal and alternate and/or emergency feeders. This equipment is used to select either the normal or alternate source of the ship service power, or to obtain power from the emergency distribution system if an emergency feeder is also provided.

Automatic bus transfer (ABT) equipment is used for loads that require two power supplies, except for cold-ship starting of auxiliaries and fire pumps, which have manual bus transfer equipment. On the steering power equipment, which is provided with a normal, alternate, and emergency power supply, manual bus transfer equipment is used to select between the normal and alternate supplies, and automatic bus transfer equipment is used to select between the ship service and emergency supplies. In some new construction only two sources of steering power are provided, they are normal and emergency. The operation of a representative automatic bus transfer unit is described later in this chapter.

The lighting circuits are supplied from the secondaries of 450/120-volt transformer banks connected to the ship service power system. In large ships the transformer banks are installed in the vicinity of the lighting distribution panels located at some distance from the generator and distribution switchboards. In small ships the transformer banks are located near the generator and distribution switchboards and energize the switchboard buses that supply the lighting circuits.

The lighting distribution system feeders, mains, and submains are 3-phase circuits, and the branches are single-phase circuits. The single-phase circuits are connected so that under operating conditions the single-phase loads on the 3-phase circuits are as nearly balanced as possible.

PHASE SEQUENCE.—The phase sequence in naval ships is ABC; that is, the maximum positive voltages on the three phases are reached in the order: A, B, and C. Phase sequence determines the direction of rotation of 3-phase motors. Reversal of the phase sequence reverses the direction of rotation of three phase motors. The phase sequence of the power supply throughout a ship is always ABC (irrespective of whether power is supplied from any of the switchboards or from the shore power connection) to ensure that 3-phase, a-c motors will always run in the correct direction.

Phase identification is denoted by the letters, A, B, and C in a 3-phase system. Switchboard and distribution-panel bus bars and terminals on the back of switchboards are marked to identify the phase with the appropriate letters, A, B, or C. The standard arrangement of phases in power and lighting switchboards, distribution panels, feeder distribution boxes, feeder junction boxes, and feeder connection boxes is in the order A, B, C from top to bottom, front to back, or right to left when facing the front of the switchboard, panel, or box and left to right when facing the rear of the switchboard, panel, or box.

SHORE POWER CONNECTION.—The number and locations of shore power connections vary on different types of ships.

Shore power connections are provided at, or near, a suitable weather-deck location to which portable cables from the shore or from ships alongside can be connected to supply power for the ship's distribution system when the ship service generators are not in operation. This connection also can be used to supply power from the ship service generators to ships alongside.

Multipurpose power circuits are provided to supply 450-volt, 3-phase power for portable hoists; portable welding units for repair, maintenance, and damage repair purposes, including underwater welding and cutting; and portable submersible pumps. The multipurpose power outlets are of the grounded type and are used with grounded plugs and cables having a ground wire that grounds the metallic case and exposed metal parts of the tool or equipment when the plug is inserted in the receptacle. The ground wire provides a conducting path of low resistance between the metal housing of the tool and the ship's structure. In the event of a casualty to the insulation of the tool, the ground wire will

11602 11601

shunt the operator, thereby protecting him from shock.

The outlets are located so that two portable pumps can be operated in any compartment by using 75 feet of cable for each pump. The outlets are fed from power distribution panels whenever practicable. A minimum number of outlets are fed from any one panel in order to provide as great a diversity of supply as possible. An adapter is provided with the 75-foot extension cables for making connections to the casualty power system if power is lost from the outlets.

Emergency Power Distribution

The following information applies to combatant ships. The majority of auxiliary ships are not so equipped.

The emergency power distribution system is provided to supply an immediate and automatic source of electric power to a limited number of selected vital loads in the event of failure of the ship service power distribution system. The system, which is separate and distinct from the ship service power distribution system, includes one or more emergency distribution switchboards. Each emergency switchboard is supplied by its associated emergency generator. The emergency feeders run from the emergency switchboards (figs. 11-1 and 11-2) and terminate in manual or automatic bus transfer equipment at the distribution panels or loads for which emergency power is provided. The emergency power distribution system is a 450-volt, 3-phase, 60-cycle system with transformer banks at the emergency distribution switchboards to provide 120-volt, 3-phase power for the emergency lighting system.

The emergency generators and switchboards are located in separate spaces from those containing the ship service generators and distribution switchboards. As previously stated, the normal and alternate ship service feeders are located below the waterline on opposite sides of the ship. The emergency feeders are located near the centerline and higher in the ship (above the waterline). This arrangement provides for horizontal separation between the normal and alternate ship's service feeders and vertical separation between these feeders and the emergency feeders, thereby minimizing the possibility of damaging all three types of feeders simultaneously.

The emergency switchboard is connected by feeders to at least one and usually to two different ship service switchboards. One of these switchboards is the preferred source of ship service power for the emergency switchboard and the other is the alternate source (fig. 11-3). The emergency switchboard and distribution system are normally energized from the preferred source of ship service power. If this source of power should fail, bus transfer equipment automatically transfers the emergency switchboard to the alternate source of the ship service power. If both the preferred and alternate sources of ship service power fails, the gas turbine or diesel-driven emergency generator starts automatically, and the emergency switchboard is automatically transferred to the emergency generator.

When the voltage is restored on either the preferred or alternate source of the ship service power, the emergency switchboard is automatically retransferred to the source that is available, or to the preferred source if voltage is restored on both the preferred and alternate sources. However this is only on certain types of ships. Some systems require the emergency generator to be tripped manually before the ABT will transfer back to the available preferred or alternate source. The emergency generator must be manually shut down. Hence, the emergency switchboard and distribution system are always energized either by a ship service generator or by the emergency generator. Therefore, the emergency distribution system can always supply power to a vital load if both the normal and alternate sources of the ship service power to this load fails. The emergency generator will not start automatically if the emergency switchboard can receive power from a ship service generator.

FEEDBACK TIE.—A feedback tie from the emergency switchboard to the ship service switchboard (fig. 11-2) is provided in most ships. The feedback tie permits a selected portion of the ship service switchboard load to be supplied from the emergency generator. This feature facilitates starting up the machinery after major steam alterations and repairs, and provides power to operate necessary auxiliaries and lighting during repair periods when shore power and ship service power are not available.

Because of the limited capacity of the emergency generators, it is not intended that the "feedback" tie is to be generally utilized to

4031411603 S08

77.165

Figure 11-3.—Emergency and ship service distribution systems interconnections.

supply power to the ship service distribution system. Use of the "feed back" tie should be limited to special circumstances such as dock conditions when it is desired to secure the ship service generators, and in cases where it is necessary to feed power through the ship service switchboards to certain auxiliaries in order to start ship service generators. When the feedback tie is used, increased vigilance is necessary to prevent overloading the emergency generators.

Casualty Power Distribution

Damage to ship service and emergency distribution systems in wartime led to the development of the casualty power system. The system provides for making temporary connections to vital circuits and equipment. The system is limited to the facilities necessary to keep the ship afloat and permit it to get out of the danger area. The system also supplies a limited amount of armament, such as antiaircraft guns and their directors to protect the ship when in a damaged condition.

The procedures for rigging and unrigging casualty power are discussed later in this chapter.

To provide you with an overall picture of power distribution, coverage is given first on one of the older DD-692 class destroyers (many of which are still in service), followed by a brief description of the DLG-23 distribution system.

A-C SWITCHBOARDS (DD 692)

A-c switchboards may consist of a single section or of several sections physically separated and connected by cables to form a switchgear group. This arrangement of sections provides greater resistance to damage due to shock. It also provides a means for localizing damage, and removal of a damaged section for repairs or replacement. Modern a-c ship service and

CONFIDENTIAL

the TILT control for a new beam tilt, one signal becomes larger than the other, cancellation is no longer complete, and therefore an error signal is developed which causes the servoamplifier to develop a control voltage for the tilt-torque motor. As the motor drives the scanner to the required tilt angle, a mechanical coupling from the motor turns the rotor of the followup synchro. When the manual-tilt synchro again cancels the resolver-synchro signal at the input of the servoamplifier, the tilt-torque motor stops. The beam-tilt angle thus obtained is determined with respect to the horizontal.

Damping Signal Generator

An a-c generator is geared mechanically to the tilt-torque motor and has an output voltage when the torque motor turns. This is the damping-signal generator shown in figure 17-37. The a-c voltage out of this generator is adjusted to a value equal to the error signal produced with only a few degrees of angular displacement between input and output shafts. This ANTIHUNT or DAMPING voltage is fed to the servoamplifier in such a manner as to be out of phase with the error voltage at all times. As the servo-torque motor turns the output shaft to its new position, the amplitude of error signal will be constantly decreasing to a null of voltage. At some point close to zero angular displacement between input and output shafts, the antihunt a-c voltage will be equal in amplitude but out of phase with the error voltage, so that the signal into the servoamplifier is canceled. The inertia of the output shaft mechanism carries the output shaft beyond this point to where the phase of the amplifier input signal is reversed and starts to increase in amplitude due to the damping signal generator's output exceeding the error signal. This causes a reversal of the output voltage from the servoamplifier to the torque motor prior to reaching a null of the positional error voltage. This reversal of torque causes a braking action which stops the torque motor and the load. This also stops the damping-signal generator and no further error is applied to the amplifier.

Some provision must be made to control the exact amplitude of the net input signal to the servoamplifier so that optimum stability is obtained. This may be done by varying the antihunt or damping generator output so as to cancel out the error signal at the proper angular displacement.

If the antihunt or damping signal is LOW in amplitude as compared to the error signal at the correct cancellation angle, the power to the torque motor will not be removed at the proper angular displacement point. This will cause the output shaft to overshoot the proper angle and oscillations or hunting will occur. These oscillations will gradually diminish to the correct position of the output shaft. If the antihunt or damping signal is HIGH in amplitude as compared to the error signal at the proper cancellation angle, the error signal will be canceled at too great an error angle, or too soon. The output shaft will be stopped with some degree of error angle remaining between input and output shafts. As the output shaft stops, the a-c damping voltage will fall to zero and the remaining error signal will cause the shaft to turn slowly to the correct point. It is of interest to note that the hunting of the scanner is held to a maximum of plus or minus one-half degree of tilt about the angle of stabilization. This, as you can easily understand, is a very close tolerance of error and thus, hunting is adequately eliminated.

GROUND STABILIZATION

Ground position indicating equipment continuously indicates the ground position of a flying aircraft from an initial reference point. One of its functions is to show north-south (N/S) and east-west (E/W) distances from the reference point on direct reading dials. Its primary function is to furnish voltages which will "ground stabilize" a radar display. This is accomplished by causing the PPI display to remain fixed geographically.

Unstabilized search radar produces a PPI display that constantly changes as the aircraft moves across an area. Since the sweep starting point represents the position of the aircraft in the center of an area, it follows that the PPI presentation will change as the aircraft travels. Also, any targets on the scope will move across the scope. If, however, a target is selected and the radar display is ground stabilized, the sweep starting point will change and the targets will remain fixed in place on the scope. The radar continues to "view" only the selected area in which the targets lie, as shown in figure 17-39. For each

emergency switchboards are of the dead-front type.

Ship Service Switchboards

The dead-front switchboard (fig. 11-4) utilizes sheet-steel panels or enclosures from which only the meters and operating handles of the switches and circuit breakers protrude to the front of the switchboard. This type of construction is used for all a-c distribution systems and for the d-c distribution systems in some large ships.

The equipment is grouped to form a number of units, each complete with a separate front panel and all the required appurtenances such as the a-c generator control unit, a-c bus tie unit, power distribution unit, and lighting distribution unit. A number of units mounted on a common base comprise a section or several sections that are physically separated and connected by cables to form a switchgear group.

A separate control benchboard (fig. 11-5) is provided in the switchgear groups for cruisers and aircraft carriers. This benchboard mounts all the generator controls equipment, all

77.166

Figure 11-4.—A-c ship service switchboard, dead front.

1160500311

27.65.1

Figure 11-5.—Control benchboard.

measuring instruments, and all the control for electrically operated equipment. This arrangement provides for a centralized control of the generators and major switching operations. The control benchboard in ships equipped with four ship service switchgear groups are provided with a mimic bus that has indicating lights to show which generator circuit breaker and which bus tie circuit breakers are closed throughout the ship. In ships not provided with a control benchboard, the metering and control equipments are mounted on the front panels of the units in the switchboards or switchgear groups. The ship service switchboards in a destroyer 692 class consists of switchgear groups 1S and 2S, located in the forward and after enginerooms respectively.

The forward ship service switchgear group (fig. 11-6) is designated as the control switchboard; it is provided with instruments and controls for the after generator to allow for dividing the load. All paralleling of the generators is accomplished at the ship service switchboard associated with the incoming generator.

The after ship service switchgear group (fig. 11-7) is similar to the forward ship service switchgear group and consists of the same number of corresponding designated panels.

Generator switchboards are equipped with meters to indicate the generator voltage, current, watts, frequency, and power factor (new construction ships do not have power factor meters). Synchroscopes and synchronizing lamps are provided for paralleling generators. Indicator lamps are provided for visual indication of the operating conditions of various circuits.

The frequency is controlled by generator speed. The speed is automatically controlled by the speed governor of the prime mover. The speed governors for large machines can be set to the required speed by a governor motor that is controlled from the switchboard.

To prevent the generator from operating as a motor when running in parallel with other generators, the generator circuit breaker is equipped with a reverse power relay that trips the breaker and takes the generator off the line when power is fed from the line to the generator instead of from the generator to the line.

Protection against overspeed is provided in the governing mechanism of the prime mover.

A voltage regulator is mounted on each switchboard and operates automatically to vary the field excitation in order to maintain the generator voltage constant throughout normal changes in load.

Some ships are provided with a standby regulator and transfer switch to provide automatic voltage regulation if the regulator in service fails. In recent construction the standby regulator has been deleted. In all installations a means is provided to manually adjust the voltage if the automatic regulator fails.

Emergency Switchboards

The emergency switchboards (not shown) are located in the forward and after emergency generator rooms respectively. The emergency switchboards provide electric power to certain vital auxiliaries and a limited

Figure 11-7.—After generator and distribution switchboard (2S).

11607

amount of lighting in the event of failure of the ship service power. The diesel generating unit starts automatically within 10 seconds after failure of the ship service power. The emergency power system is arranged for automatic transfer of the circuit for the steering power panel to the emergency generator. The forward and after emergency switchgear groups are normally energized from the forward and after ship service switchgear groups respectively.

The forward emergency switchgear group controls the forward emergency diesel generating unit; the forward ship service and emergency bus transfer equipment; the local emergency power bus feeders; the remote emergency power bus feeders; and the emergency lighting feeders.

The after emergency switchgear group controls the after emergency diesel generating unit; the after ship service and emergency bus transfer equipment; the special emergency power bus feeder; the emergency power bus contactor; the local emergency power bus; the remote emergency power bus feeders; and the emergency lighting feeders.

The generator panels of both the forward and after emergency switchboards are provided with an a-c voltmeter and a voltmeter transfer switch to permit reading the (three) phase-to-phase voltages in the a-c generators, or the voltage of the local emergency power bus on the forward emergency switchboard and the special emergency power bus on the after emergency switchboard. Both emergency switchboards are also provided with an a-c ammeter and an ammeter transfer switch to permit reading the current in the three phases of the emergency generator, an a-c wattmeter for reading the power of the emergency generator, and a frequency meter for reading the frequency of the local power bus on the forward emergency switchboard and the special emergency power bus on the after emergency switchboard.

Interconnections

The connections between the ship service and the emergency generating units and their associated switchboards and the interconnections between the switchboards are illustrated in the schematic line diagram in figure 11-8. The a-c buses on the forward and after ship service switchboards can be connected together, and the d-c buses on these switchboards can also be connected together. This arrangement enables one generating unit to supply power to both ship service switchboards when the other unit is out of service, and also provides for parallel operation of the two ship service generating units (1SG and 2SG). However, when operating split plant the generators are operated separately, each unit supplying power for its own section of the ship. In recent construction the emergency switchboards have only one bus; however, older types may have two, the local and remote buses.

Each emergency generator (1EG and 2EG) is connected to the bottom studs of a generator circuit breaker. The top studs of the generator circuit breaker are connected to one side of the ship's service and emergency generator automatic bus transfer equipment (ABT). The other side of this bus transfer equipment is connected to the feeder from the forward ship service switchboard (1S) for the forward emergency switchboard (1E) and to the feeder from the after ship service switchboard (2S) for the after emergency switchboard (2E). The midpoint of the bus transfer equipment is connected to the 450-volt local bus on the forward emergency switchboard and to the 450-volt special bus on the after emergency switchboard. The special bus on the after emergency switchboard supplies power to the steering power transfer switchboard (not shown) through a type AQB circuit breaker and is connected to the 450-volt local bus through the bus contactor.

A 450-volt remote power bus is provided on each emergency switchboard (for example, 1E) and is supplied from the local bus of the second emergency switchboard (2E) to allow for the transfer of emergency power from one emergency generator to the other emergency switchboard to supply certain auxiliaries. This tie feeder is controlled by a type AQB circuit breaker connected to the local bus of one emergency switchboard (2E) and by a type NQB circuit breaker connected to the remote bus of the other emergency switchboard (1E). Certain feeders, such as gun mounts, I.C. switchboards, and emergency lighting transformers, are connected by means of mechanically interlocked type AQB circuit

77.169

Figure 11-8.—Ship service and emergency switchboard interconnections.

11609

breakers to either the local or remote emergency power buses. The mechanical interlocks prevent both circuit breakers from being closed at the same time so that the emergency generators cannot be paralleled.

The type NQB feedback circuit breaker must NOT be closed if the white indicator light (not shown) is lighted to indicate potential on the feeder from the ship service switchboard connected to the particular emergency switchboard. Otherwise, the ship service generator could supply power to the emergency generator. Also, when an emergency generator (for example, 1EG) is used to supply limited power to the associated ship service switchboard (1S) through the feedback circuit, the type ACB ship service generator circuit breaker (A1) and the type ACB bus tie circuit breaker (D1) to the remote ship service switchboard (2S) must NOT be closed. If the a-c generator circuit breaker is closed, power could be fed to the 1SG ship service generator, which is not operating. If the a-c bus tie circuit breaker is closed, the emergency generators can be paralleled or power can be fed to circuits connected to the after ship service switchboard.

A casualty power terminal and a type AQB casualty power circuit breaker are located on the forward emergency switchboard and on the after emergency switchboard. The terminals are used for connecting casualty power cables to supply power to or from the emergency switchboards. The casualty power circuit is connected to the local emergency power bus on the forward emergency switchboard and to the special emergency power bus on the after emergency switchboard.

A shore power circuit breaker, H2, is located on the after ship service switchboard. A connection box is provided on deck so that the ship service switchboards can be energized from the shore or from another ship. This connection can be used also to supply power from either ship service switchboard to the shore or to other ships alongside.

Automatic Bus Transfer Equipment

Power to the emergency switchboards can be supplied from the associated ship service switchboard or from either emergency generator. An automatic bus transfer controller (ABT, fig. 11-9) is mounted on each emergency switchboard and is normally set to select power from one of the ship service switchboards for the emergency distribution section. If a loss of power occurs from the associated ship service switchboard supply, the automatic bus transfer controller will start the diesel emergency generator, remove the ship service supply from the local emergency power bus, and connect the emergency diesel generator to the local emergency power bus. The vital loads are shifted either automatically or manually at the loads, to the emergency supply. When the ship service voltage is restored, the emergency generator is automatically disconnected, and the emergency switchboard is again energized from the ship service switchboard.

The standard bus transfer controller (fig. 11-9) consists of (1) a motor-operated contactor unit and (2) a separate control panel designed for mounting in dead-front switchgear.

Some emergency switchboards are equipped with electrically operated circuit breakers in lieu of contactors such as the one shown in figure 11-9.

The contactor unit (fig. 11-9,A) consists essentially of two 3-pole, cam-operated contactors for main line connection; six auxiliary cam-operated contacts for control and indicating light circuits; two pilot motors for automatic operation; and a handwheel for manual operation. The two sets of main contactors are operated from a camshaft that is driven by the two pilot motors. When the camshaft moves from one extreme position to the other, the cams open one contactor and close the other contactor by means of springs. Both contactors cannot be closed at the same time but both can be open. One pilot motor drives the shaft in one direction and the other motor drives it in the opposite direction. The auxiliary contacts are used to control the contactor-position indicator lights, and to deenergize either motor when the shaft reaches the limit of its travel. An automatic-manual transfer switch permits manual operation of the bus transfer controller. The control panel (fig. 11-9,B) consists of an insulating base on which are mounted two voltage-sensitive relays with associated rectifiers and transformers.

The setup for automatic operation of the bus transfer equipment located on the after emergency switchboard in a 692-class destroyer is illustrated in figure 11-10. The

11609

Figure 11-9.—Automatic bus transfer controller. 77.170

voltage-sensitive relays, VN and VE, have two operating coils connected in series and four (three a and one b) contacts. When the relay is energized, the a contacts are closed and the b contacts are open. Conversely, when the relay is deenergized, the a contacts are open and the b contacts are closed. Relay VN (fig. 11-10) is shown in the energized position and relay VE in the deenergized position. The relay is d-c operated by means of a 450/160-volt transformer and copper oxide rectifier. Relay VN is operated by transformer T1 and rectifier CR1 and relay VE is operated by transformer T2 and rectifier CR2. The VN relay, connected in the after ship service supply, is

11611

77.171

Figure 11-10.—Automatic bus transfer equipment in after emergency switchboard.

adjusted to pick up at 395 volts and drop out at 290 volts. The VE relay, connected in the emergency supply, is adjusted to pick up at 420 volts.

The automatic-manual transfer switch (AM1) has three contacts. When the transfer switch is in the AUTOMATIC position the contacts are closed, and when the switch is in the MANUAL position the contacts are open and prevent operation of the pilot motors. This switch is shown in the AUTOMATIC position. One pair of contacts (1-2) is in the circuit of motor N, one pair (3-4) in the circuit of motor E, and the other pair (5-6) is in the circuit of the transformer supplying the setup indicator light (not shown). This light indicates when the setup is properly made for automatic operation of the emergency diesel generator and the bus transfer equipment.

A time delay relay, TD, having a single coil and two pairs of contacts, b and b1, is connected in the circuit of the bus transfer equipment to delay the starting of the emergency diesel generator, and to delay the energizing of the rectifier for relay VE. The time delay on dropout is approximately one second (not adjustable). The relay is d-c operated by means of a 450/160-volt transformer (T-3) and copper oxide rectifier (CR3).

Under normal conditions, with either or both ship service turbine generators in operation, the two emergency diesel generators will not be running, and the emergency switchboards will be supplied with power from the forward and after ship service switchboards through the ship service and emergency bus transfer equipments located on the emergency switchboards. Hence, when the supply from the after generator switchboard is 290 volts or above, relay VN will be energized, contactor N will be closed, and the 450-volt local emergency power bus will be fed from the after ship service switchboard. With contactor N normally closed, the pilot motor for contactor N will be deenergized as the cutoff contact for contactor N will be open. If the supply voltage should fall to 290 volts or below, relay VN will drop out and open its a3 contact, which opens the circuit to rectifier CR3 that supplies relay TD.

After a brief interval, relay TD closes its b contact to complete the circuit to rectifier CR2 for relay VE. At the same time contact b1 closes to complete the starting circuit to the emergency diesel generator (not shown). The b contact of relay TD is also in the circuit to the pilot motor for contactor E. However, this motor is not energized until contact a1 of relay VE closes. When the emergency generator voltage increases to 420 volts or above, contact a1 of relay VE closes to complete the circuit to the pilot motor for contactor E. Pilot motor E will rotate the cam to open contactor N and close contactor E. At the same time, auxiliary cutoff contact, N, closes. When contactor E closes, its cutoff contact opens the circuit to the pilot motor for contactor E. The 450-volt local emergency power bus on the after emergency switchboard is now supplied from the emergency generator.

If the voltage of the preferred supply should rise to 395 volts or above, relay VN will pick up and close its a1 contact to complete the circuit to the pilot motor for contactor N. Motor N will rotate the cam to open contactor E and close contactor N. When contactor N closes, its cutoff contact opens the circuit to the pilot motor for contactor N. Because contact a3 is now closed, CR3 and relay TD will be energized. Contact b of relay TD will open and deenergize the circuit to rectifier CR2, thereby deenergizing relay VE opening the circuit to pilot motor E. However, the emergency diesel generator will continue to run until it is shut down manually.

Ground Detector Lamps

A set of three ground detector lamps (fig. 11-11) connected through transformers to the main bus of each ship service switchgear group and to the emergency bus provides a means to check for grounds on any phase of the 3-phase system.

To check for a ground, turn switch S on and observe the brilliancy of the three lights. If the lights are equally bright, all lights are receiving the same voltage, and no ground exists. If lamp A is dark and lamps B and C are bright, phase A is grounded. In this case, the primary of the transformer in phase A is shunted to ground and lamp A receives no voltage. Similarly, if lamp B is dark and lamps A and C are bright, a ground exists on phase B. If lamp C is dark and lamps A and B are bright, a ground exists on phase C.

POWER DISTRIBUTION ON A DLG

Figure 11-12 is a one line diagram of the radial type ship service power distribution system as found on the DLG-23, USS HALSEY. This diagram shows in simplified form the electrical system with its interlinking power circuits and emergency connections. All ship service 60 cycle power utilized on this class of ship passes through switchgear groups 1S, 2S and the emergency switchboards 1E and 2E.

Ship Service Electric Plants

The forward electric plant consists of ships service generators 1A, and 1B, and ship

77.252

Figure 11-12.—Power distribution (60 cycle) system on the DLG-23.

11614 11613

Figure 17-39. —Ground position indication display sequence.

6911 1159

service switchgear group 1S, located in the forward (No. 1) engineroom.

The after electric plant consists of ships service generators 2A, and 2B, and ships service switchgear group 2S, located in the after (No. 2) engineroom.

The four ships service generators are 1000 kw, 450 volts, 1604 amperes, 3 phase, 60 cycle, steam turbine driven, totally enclosed with an air to water heat exchanger. They are class H insulated.

Emergency Electric Plants

The forward emergency plant consists of the emergency generator 1E and the emergency switchboard 1E. The emergency generators are physically separated as far as possible from the ship service generators, and each other, to protect against simultaneous damage to the ship's electrical system from a single source. Both the forward emergency generator 1E, and the after emergency generator 2E, are rated 300 kw, 450 volt, 60 cycle, 3 phase. The forward emergency generator is driven by a gas turbine and the after emergency generator is driven by a diesel engine. In figure 11-12 the normal and alternate supplies of the emergency switchboards are labeled, to show these bus feeders from the ship service switchgear groups. The three circuit breakers shown on 1E emergency switchboard are electrically interlocked when the emergency switchboard is set up for automatic operation. While 1E or 2E is set up for automatic transfer, if the normal ship service supply drops to 300 volts or below, the load is automatically transfered to the alternate supply if 400 volts or above are available from the alternate source. If 400 volts or above are restored to the normal supply the load will automatically retransfer to the normal supply. If both ship service supplies fail or their voltages drop below 300 volts, the transfer operates automatically through relays to start the emergency generator and connect it to the emergency switchboard. If the emergency generator is supplying the emergency switchboard and ship service power is restored, retransfer will not take place, but can be accomplished by manually tripping the emergency generator circuit breaker. The operation of 1E or 2E is the same.

Interconnections

When the ship service plants are secured and shore or tender power is not available, the emergency generators can "feed back" power to either switchgear group by means of a bus transfer selector switch on the emergency switchboards. The bus transfer selector switch when placed in the manual position, allows manual operation of the circuit breakers on the emergency switchboards. While the bus transfer selector switch is in the normal preferred or alternate preferred position, the three circuit breakers on the emergency switchboards are interlocked and only one of them can be closed at a time. The feedback circuits should only be used in special circumstances such as to supply power to the ship service bus for starting the ship service plant. When the feedback provision is in use, increased vigilance must be observed to prevent overloading of the emergency generators. The feed-back circuits must NEVER be used to parallel the emergency generators with each other, with the ship service generators, or with shore power.

System Operation

The ship service generators may be run either singularly or in parallel with each other. It is possible to run all four ship service generators in parallel (parallel 1S and 2S via the bus tie), however no more than three generators can be safely operated in parallel without exceeding the interrupting capacity of the circuit breakers. The ship service generators should never be paralleled with shore power or the emergency generators.

The ship service switchgear groups and the emergency switchboards are the dead-front type. Figure 11-13 shows the 1SA section of the 1S switchgear group and figure 11-14 is the 1SB section. If one section is damaged, it may be isolated from the undamaged section by using the disconnect switches as shown on figure 11-12.

Figure 11-15 shows a disconnect device in both the open and closed position. The disconnect devices should NEVER be opened or closed on a hot bus. When operating a disconnect device it should always be either

11615

77.253

Figure 11-13.—Ship service switchgear group No. 1S: section 1SA.

completely open or completely closed. The locking springs, as shown in figure 11-15, lock the device to prevent accidental opening or closing due to vibration, if the device is operated completely in either direction until the locking spring is compressed.

Shore Power Connections

The DLG 23 is equipped with three topside shore power terminal boxes. Two of the shore power terminals (one 800 and one 400

11615
11616

77.254

Figure 11-14.—Ship service switchgear group No. 1S, section 15B.

amperes) connect to the bus tie circuit between 1S and 2S as shown in figure 11-12. The other shore power connection (800 ampere) is connected to the 2SA section of switchgear 2S via a AQB-A800 ampere frame circuit breaker.

The back of each emergency switchboard (fig. 11-16) is provided with one casualty power terminal and each ship service switchgear group is provided with four casualty power terminals installed on the back of the units (2 for each section (fig. 11-17)) and

11618
11617

77.255

Figure 11-15.—Disconnect device.

connected to the buses through 250-ampere frame size AQB circuit breakers.

Figure 11-18 shows an ACB-1600 circuit breaker in the normal operating position. Figure 11-19 shows the same breaker in the withdrawn position. The provision for drawing out the breaker to perform routine maintenance or even complete removal of the breaker is a great improvement over the older type ACB breakers as discussed previously in chapter 8. The DLG-23 has eight ACB-1600 circuit breakers in switchgear group 1S and seven ACB-1600 circuit breakers in switchgear 2S. The emergency switchboards also have drawout circuit breakers as shown in figure 11-20.

400-Cycle Power Distribution

In addition to the 60-cycle power supplied by the ship service and emergency generators, the DLG also has 400 cycle systems. The 400-cycle power is generated by motor generator sets and distributed via special frequency switchboards (fig. 11-21) to the various 400-cycle equipments. The DLG has three 200-kw, 400-cycle, 450-volt, 3-phase motor generators which supply the ship service 400-cycle power. These three motor generators, numbered M/G 1, M/G 9, and M/G 13 in figure 11-22, supply power to ship service special frequency switchboards 1SF, 5SF, and 6SF, respectively. Motor generator M/G 9 is considered a standby set which can supply 1SF or 6SF, or can be operated in parallel with M/G 13. M/G 9 or M/G 13 may be paralleled momentarily with M/G 1 when transferring the load. Figure 11-22 is a simplified one line diagram of the 400-cycle ship service system bus tie interconnections. The circuits being fed from the 400-cycle

11618

77.256

Figure 11-16.—Emergency switchboard 1E, rear view.

ship service switchboards are deleted from the figure for simplicity. Switchboard 1SF supplies the missile, fire control, ASROC and IC circuits in the forward part of the ship, and 6SF supplies the weapons circuits in the after part of the ship. The DLG also has six 60-kw, 450-volt, 3-phase, 400-cycle motor generator sets for missile fire control radar. Three of these sets (numbered 5, 7, and 8) feed the missile illuminator power switchboard (2SF) forward, and three sets (numbered 10, 11 and 12) supply the missile illuminator power switchboard (4SF) aft. Motor generator number 8 is the forward standby set and number 12 is the after standby set. The weapons control IC switchboard receives its normal 400-cycle power from a separate 60-kw motor generator set (M/G 14) via switchboard 3SF and automatic bus transfer equipment. In the event of a power loss from M/G 14, the weapons IC switchboard power supply is transferred by automatic bus transfer

to its alternate power supply, which is from 6SF. Provisions are made on the DLG-23 for future installation of yet another 400 cycle motor generator set to be designated M/G 6. M/G will be the power supply for NTDS (Naval Tactical Data Systems) when installed. There has been a tremendous increase in the number and size of special frequency (400 cycle) motor generator installations in recent years, primarily due to the increased power requirements of modern weapons systems.

77.262

Figure 11-22.—Bus tie connections on 400-cycle ship service system.

The DLG of today is just one of the newer type warships with a greatly increased capability for generation and distribution of electrical power, both 60 and 400 cycle. Although it is not possible to cover the entire electrical distribution system of a DLG in just part of a chapter, the lighting distribution, steering power, and circuits to vital auxiliary equipment are basically the same as on any other warship.

VOLTAGE REGULATORS

A voltage regulator consists essentially of a control element and associated mechanical or electrical means to produce the changes in the generator field current that are necessary to maintain a predetermined constant generator terminal voltage. When used on d-c generators, the functions performed by voltage regulators and their auxiliary equipment are to maintain the generator terminal voltage within specified limits and to provide for proper division of the load between generators operating in parallel. When used on a-c generators the functions performed by voltage regulators and their auxiliary equipment are to maintain the generator terminal voltage within specified limits, and to provide for proper division of the reactive current between generators operating in parallel.

The types of voltage regulators used in naval ships are (1) the indirect acting rheostatic, (2) the direct acting rheostatic, (3) the rotary amplifier, and (4) the combined static excitation and voltage regulation system.

The indirect acting rheostatic type voltage regulators were used on all a-c ship service generators and many emergency generators until 1943. Many of these voltage regulators are still in service, but the indirect acting rheostatic type is no longer used for new installations. The present practice for a-c generators is to use the direct acting rheostatic type, the rotary amplifier type, or the combined static excitation and voltage regulation system. The type used depends on which is considered most suitable for a particular application. Voltage regulators for d-c generators are usually of the direct acting rheostatic type.

When voltage regulators are used for either a-c or d-c generators, one regulator is provided for each generator that is to be regulated. In some ship service installations a spare voltage-sensitive (control) element is installed on the switchboard. The switchboard is provided with a transfer switch so that a spare element can be placed in service

11632

if the normal control element becomes deranged. Spare control elements are not installed for voltage regulators used on emergency generators. On later ships the spare element has been omitted.

The static excitation and voltage regulator system furnishes the a-c generator field current by rectifying a part of the a-c generator output. This output is fed to the field as a self-excited generator, after initial flashing from a battery or other source of low voltage direct current, to build up the voltage. The control element is a network of capacitors, reactors, and resistors, and it controls the field current by means of magnetic amplifiers. This system eliminates the rotating exciter and other moving parts and replaces them with an assembly of static components.

Recently developed static voltage regulators using silicon-controlled rectifiers and transsistors has reduced the size and weight of regulators as compared with designs using magnetic amplifiers. These new regulators are being evaluated on a new destroyer escort class ship. Only the indirect and direct types of voltage regulators will be described in this chapter. The other types of voltage regulators are discussed in Electrician's Mate 1 & C, NavPers 10547 (revised).

Indirect Acting Type

The indirect acting rheostatic type of voltage regulator has a voltage-sensitive element. This element controls (1) a motor-operated rheostat for changing field resistance and (2) relays that cut large blocks of resistance into or out of the field circuit in order to lower or increase the generator voltage quickly. Figure 11-23 shows the circuit for this type of voltage regulator on an alternator. When the a-c voltage is normal, the contact arm is in the vertical position, and none of its contacts touch the constantly rotating cam, because the pull of the torque motor is exactly balanced by the adjusting spring. Hence, none of the relays operate, and the rheostat motor is stationary. If the line voltage drops below normal, the pull of the torque motor becomes less and is overcome by the spring. The contact arm swings over until the decreased tension of the spring is just balanced by the torque motor. If it is a small drop in voltage, one of the contacts makes intermittent contact with the tips of the notched cam.

This action sends current impulses through the RAISE relay, which causes its contacts to open and close. This energizes the rheostat motor through its raise field, and the rheostat motor drives the sliding contacts of the field rheostat so as to shunt out more of the resistance. The impulses to the motor from the raise relay cause a stepping action of the motor, thus preventing overtravel when only a small movement of the rheostat is needed. As the field excitation increases, the a-c voltage returns to normal, and the torque motor pulls the contact arm back to the vertical position. This opens the contacts and stops the movement of the rheostat motor.

If the a-c voltage goes too high, the contact arm swings the opposite way and operates the LOWER relay, which energizes the lower field on the rheostat motor and increases the resistance, thereby decreasing the field excitation and reducing the generated voltage.

When a sudden large drop (over 5 percent) in generated voltage occurs, the contact arm is pulled over hard by the adjusting spring. This brings the front contact into continuous contact with the notched cam so that the rheostat motor runs steadily in the proper direction to correct for the voltage drop. However, to provide instantaneous compensation for this voltage drop, the high-speed relay is brought into operation. With a large deflection of the contact arm a back contact is brought into contact with a smooth surface, completing the circuit to the RAISE high-speed relay.

This relay operates, and its contacts shunt out a portion of the variable field resistance. A sudden decrease in field resistance results in a large increase in field excitation and a fast rise in the generated a-c voltage results. But when this voltage approaches normal, the torque motor opens the circuit to the high-speed relay, which in turn opens the shunted portion of the field resistance. During this time the rheostat motor continues to operate but at a steady rate instead of with its usual pulsing movements. When the generated voltage approaches within 5 percent of normal, the high-speed relay opens, and the rheostat motor completes the voltage adjustment.

Similar action takes place when the generated voltage increases over 5 percent, except that the lower relays are energized. When the high-speed lower relay operates, it removes a shunt from a fixed portion of the field resistance, which causes a large decrease

1623

77.173

Figure 11-23.—Indirect acting voltage regulator on a-c generator.

in field excitation and the resultant fast drop in generated voltage.

Direct Acting Type

The SILVERSTAT, a direct and quick-acting voltage regulator is used for both ship service and emergency generators (fig. 11-24). In large alternators the regulating resistance is connected in the shunt-field circuit of the exciter. In small machines that use these regulators the resistance may be connected directly in series with the alternator field. The torque element of the Silverstat regulator

11624

mile of flight, the origin (start) of the sweep is displaced 1 mile on the indicator in the direction of flight. Thus, the track of the sweep origins becomes the aircraft's flightpath.

Automatic ground stabilization is particularly advantageous in some radar applications. It simplifies the problems of ASW operation by reducing calculations required to fly a sonobuoy pattern; it enables the operator to easily establish a track of moving targets such as ships, surfaced submarines, vehicles on land, and airborne aircraft; and also, the ground stabilization feature can be used as a homing device from reasonable distances.

The purpose of a ground stabilization system is to combine and amplify certain d-c voltages which are used to properly position the start of the sweep on the indicator. These d-c voltages are developed either by manual control of slew helipots or by automatic control from the ground stabilization computer.

Four slewing voltages (representing the cardinal directions) are supplied and controlled automatically by the associated ground stabilization computer. These voltages are combined with another set of four slewing voltages which are manually controlled by the radar operator with the manual slew helipots. The combined voltages are applied to the grids of the input cathode followers, the outputs of which are applied to pairs of push-pull d-c amplifiers which determine the bias voltages for the associated sweep amplifiers in the indicator deflection system. The starting position of the sweeps on the indicator changes as these biases change, and varies automatically with respect to aircraft speed, direction of flight, and wind velocity. (See fig. 17-40.)

COMPUTER

As can be seen from figure 17-40, the computer unit is the "heart" of the ground position indicator (GPI) system. Since a discussion of computers is contained in chapter 10 of this course, only its block diagram will be discussed.

The airborne dead-reckoning computer continuously determines ground position from an initial starting point. All of the information necessary for its operation is contained within the aircraft. The necessary data to operate the computer are (1) magnetic heading of the aircraft, supplied by the magnetic compass; (2) airspeed, supplied by the pitot pressure; (3) local magnetic variation, which is manually inserted to change magnetic heading to true heading; and (4) windspeed and wind direction, which are also manually inserted.

Airspeed Channel

In performing its operations, the computer considers true airspeed, true heading, and time. The resolvers in the computer are circuits designed to break up a vectorial quantity into two components. The outputs are the sine and cosine values of the quantity. The airspeed channel receives information from the pitot pressure and resolves this information into true airspeed. The servomotor then positions the N/S and E/W potentiometers in the heading channel to a value that represents true airspeed.

Heading Channel

Magnetic heading obtained from the aircraft's compass system is corrected to true heading in the heading channel. Voltages proportional to the directional components (N/S and E/W) of true heading, derived from a sine-cosine resolver, are applied to the dual sections of the airspeed potentiometers. The shaft of this potentiometer is positioned by the output of the airspeed channel. As a result, the output voltage of one section is proportional to the N/S component of airspeed, while the output voltage of the second section is proportional to the E/W components of airspeed.

Wind Channel

Up to this point the computer has determined and combined true airspeed and true heading, and has developed outputs that are the sine and cosine of the vector addition. In order to determine groundspeed, it is necessary to insert the direction and speed of the wind. Wind data may be obtained by any of several methods, including aerology and drift sights. These two factors (speed and direction) are inserted into the wind channel manually, and the resolver's outputs energize the N/S and E/W sections of the wind potentiometer.

Summing Network

The two inputs to each summing network are the components necessary to determine groundspeed. The inputs are derived from true heading, true airspeed, and wind data

cell 1160

73.56

Figure 11-24.—A Silverstat voltage regulator on an a-c generator.

consists of a control coil operated by a direct current obtained from a Rectox rectifier. A movable core is mounted on an aluminum armature in such a manner that it can move in the air gap of the magnetic circuit of the control coil. The magnetic pull on the armature is balanced by the adjusting spring. A driving member is mounted on the upper end of the armature and bears against an assembly of silver buttons. Each silver button is mounted at the free end of an individual leaf spring of conducting material. The leaf springs are individually insulated. A connection is made from the fixed end of each leaf spring to a tap on the regulating resistance, which is in series with the shunt field of the exciter.

When the top of the moving arm is at the left-hand end of its travel, the driving member allows the free ends of the leaf springs, which carry the silver buttons, to rest against a stop of insulating material. In this position the free ends and the silver buttons are separated from one another. As the moving arm travels to the right, the driving member bears against the silver-button assembly, which closes the silver buttons together successively and in sequence. When the moving arm reaches the right-hand limit of travel, all the buttons are in firm contact with one another. As the driving member travels back to the left, the buttons successively move apart, in sequence, from one another. Only a travel of a fraction of an inch is required to close or open all the buttons in sequence. Although the operation of the silver buttons in sequence appears to cut small steps of resistance in or out in a definite step-by-step manner, its operation does not actually do so. As the buttons are operated by the moving arm, there is a progressive change in pressure between the faces of the buttons. This change in pressure between the silver surfaces varies the effective

11625

resistance, which amounts to varying the field resistance in almost infinitesimal steps.

For a given value of regulated voltage and load on the machine being regulated there is a corresponding value of regulating resistance required in the field circuit and a corresponding position of the moving arm and silver buttons which will give this value of resistance. Under such conditions the magnetic pull on the moving arm is balanced against the spring pull at the position of its travel. When a load change occurs on the regulated machine, a corresponding change in terminal voltage occurs. To restore the voltage to its correct regulated value, the moving arm and the silver buttons take a new position because of the unbalance between the spring pull and the magnetic pull on the moving arm.

If the voltage of the alternator rises, the armature is drawn farther into the air gap of the magnet. This causes the driving member to reduce its pressure on the leaf springs, opens some of the short-circuiting silver buttons, inserts more resistance into the exciter field, and restores the voltage to its correct value. Should the alternator voltage drop, the process is reversed.

D-C ELECTRIC POWER SYSTEMS

Although a-c power systems have replaced d-c power systems in combat ships, d-c power is still widely used in auxiliary ships having considerable deck machinery. The d-c power systems in auxiliary ships are not ordinarily required to maintain the high degree of reliability required for combatant ships. However, the degree of reliability is carried out within the limits of practicability and depends on the type and size of the ship.

The d-c electric power systems installed in surface ships are the (1) low-voltage system, (2) 120-volt, 2-wire system, and (3) 120/240-volt, 3-wire system.

LOW-VOLTAGE SYSTEM

The low-voltage (12 volt or 24 volt) system is installed in motor torpedo boats, small landing craft, and small boats. Power is supplied by generators that are driven by the propulsion engines or by small auxiliary engines. Storage batteries are used to supply power to the system when the generators are not operating.

120-VOLT, 2-WIRE SYSTEM

The 120-volt, 2-wire system is usually installed in ships in which the total electrical load is small or in ships in which the 120-volt load is the major part of the connected load. The power loads are usually supplied by feeders running directly from the switchboard. The lighting in the forward and after part of the ship is usually supplied by feeders running to lighting distribution boxes near the centers of the forward and after loads.

120/240-VOLT, 3-WIRE SYSTEM

The 120/240-volt, 3-wire system was formerly installed in all large surface ships. This system is still in use in older ships and in converted merchant ships with large deck machinery loads that warrant the use of d-c power. The 120/240 volt, 3-wire system is lighter in weight, smaller in size, and more efficient in operation than the 120-volt, 2-wire system.

In the 3-wire system the power is generated by a 120/240-volt, 3-wire, d-c generator or a converted 240-volt, 2-wire, d-c generator provided with a transformer balancer (center tapped autotransformer) connected through slip rings to tapping points on the generator armature, which establishes a neutral. The present Navy practice is not to ground the neutral (or either leg) of a 3-wire system. The positive, neutral, and negative polarities of bus bars and terminals are indicated + (black), ± (white), and - (red) respectively.

Power distribution from the switchboards to the power loads is a 240-volt, 2-wire system. The 120-volt distribution from the switchboards to the distribution panels is a 120/240-volt, 3-wire system and from the distribution to the branch circuits is a 120-volt, 2-wire system. The 120-volt, 2-wire branch circuits for lighting and appliances are balanced on the two sides of the neutral.

D-C SWITCHBOARDS

An outstanding feature of reliability in combat ships is the installation of two or more independently operated ship service

11626

switchboards and associated generators located in different parts of the ship. On the other hand, auxiliary ships are usually provided with one switchboard and associated generators located in the main engineroom or adjacent auxiliary machinery space.

The schematic diagram of connections for a typical generator and distribution switchboard shown in figure 11-25 illustrates the following features of control and protection:

1. Generators are connected to the power distribution system through circuit breakers which are designed to automatically disconnect them from the bus under predetermined conditions for overload or short circuit.

2. Reverse current trips integral with the circuit breaker protect the generators against motorizing when operating in parallel.

3. Disconnecting switches permit the circuit breakers to be isolated from the bus for service and repair.

4. Circuit breakers with automatic tripping devices are provided on all distribution circuits to isolate circuit faults.

27.66

Figure 11-25.—Simplified schematic wiring diagram of d-c switchboard.

11628
11627

5. Voltmeters are connected through selector switches to measure generator and bus voltages.

6. Two ammeters are provided with three-wire generators to measure the current in the positive and negative leads. These ammeters are connected into the line through suitable shunts.

7. Generator field rheostats are connected in series with the shunt field circuits for purposes of adjusting generator voltage.

8. Indicating devices include circuit breakers, indicating lights, and ground detector lights.

Ship service switchboards on the larger ships contain many more distribution circuits than shown in figure 11-25. The feeder breakers are grouped in accordance with size and the load which they serve. Where there is a large lighting load, a segregation between lighting and power is made by including separate buses and separate panels.

Circuit breakers are sometimes used to provide backup protection for feeder circuit breakers in applications where the available short circuit current exceeds feeder breaker interrupting capacities. It is undesirable to use too many of the larger breakers because of space limitations.

Feeder breakers to machinery space ventilation panels on the larger auxiliary ships are provided with shunt trips operated from push-button stations outside the machinery spaces. This feature is included as an aid to the control of fires in the machinery spaces.

Live Front

The live-front switchboard (fig. 11-26) utilizes panels composed of an insulating material on which are mounted the knife switches, circuit breakers, fuses, meters, indicating devices, and other components. This type of construction was formerly used for all ships, but is now generally found only aboard the older auxiliary ships and service craft. All new construction, regardless of the voltage is of the dead front-type.

Dead Front (Ship Service)

The electric plant in an AP-type auxiliary ship consists of three turbine-driven ship service generating units located in the main

engineroom. The ship service d-c generators are 300-kw, 120/240-volt, 3-wire units equipped with center-tapped autotransformers connected across slip rings.

The main generator and distribution switchboard is the dead-front type and consists of three combined generator and power-feeder panels, one feeder panel, one backup ACB panel, and two combined lighting and power feeder panels (fig. 11-27). The switchboard provides for single and parallel operation of the main generators and for control of the power and lighting feeders emanating from the backup power and lighting buses.

The generators are controlled from panels I, II, and III and furnish 120/240-volt power to the ACB backup circuit breakers B1, B2, B3, and B4 on panels I and VI. Panels I and VI furnish 120/240-volt, 120-volt, and 240-volt power to panels IV, V, and VII and the lower portions of panels II and III. All circuits are protected with manually operated circuit breakers. These circuit breakers are equipped with overcurrent devices that operate to open the respective breaker on short circuit or sustained overload. In addition to the overcurrent devices, each generator breaker is equipped with a direct-acting reverse current device, an undervoltage device, and an overspeed device to trip the breaker on current reversal, undervoltage, or overspeed, respectively.

The backup circuit breakers should be closed at all times. If the feeder breaker and backup breaker open on a short circuit, the feeder breaker should be checked to determine that it is in satisfactory operating condition before closing the backup breaker.

The switchboard meters installed for observing the performance of d-c generators usually include only voltmeters and ammeters. The generator speed is controlled by the governor of the prime mover. Remote speed control is not required, and no governor motor control switch is used on the switchboard as with a-c generators. Manual voltage control is obtained by a rheostat in the shunt field. This rheostat is operated at the switchboard. D-c generators are usually not provided with voltage regulators. The inherent characteristics of the generators provide all the voltage regulation that is necessary in most applications. Disconnect links, located on the back of the switchboard are provided for each generator circuit to isolate the generator circuit breaker and associated devices for maintenance and repairs.

Ground Detector Lamps

The neutral of the main power system is grounded in this AP type of auxiliary ship. The ground connection (fig. 11-28) is made through a ground contactor (normally closed) that is connected in series with a parallel combination comprising a current-limiting resistor and a ground circuit breaker (normally closed). The ground circuit breaker has an instantaneous trip device. If a ground occurs on either the positive or negative side of the system, the instantaneous trip device will open the ground circuit breaker and insert the resistor in the neutral ground circuit. The resistance is of sufficient magnitude to limit the ground current to one percent of the rated full-load current of the generator.

The purpose of the ground contactor is to disconnect the neutral ground when ground tests are being made (by means of the ground detector voltmeter or the ground lamps) to determine if any grounds exist on the system.

A ground lamp test pushbutton, PB, is provided for making ground tests with the ground detector lamps, A and B. When the pushbutton is held closed, the operating coil, G, of the ground contactor is energized and opens contacts G to remove the neutral ground. At the same time, contacts G1 close and place ground on one side of the ground lamp circuit.

An alarm system is provided to indicate operation of the ground circuit breaker, CB. When the ground circuit breaker is tripped

77.177

Figure 11-28.—D-c ground detector lamp circuit.

0501 111630

by a ground fault, it opens contacts CB1 and CB2 and closes contacts CB3. When contacts CB1 open, the mechanical interlock opens contacts CB2, which remove a shunt from the ground alarm lamp, R, allowing it to light. When contacts CB3 close, the circuit to the alarm bell is energized.

The alarm system includes an alarm reset relay, A, and pushbutton APB. When the reset relay pushbutton is operated, contacts A close to maintain the operating coil A energized, and contacts A1 open to deenergize the alarm bell. The alarm lamp, R, remains lighted at all times when the ground circuit breaker, CB, is open. The alarm bell does not sound when the ground circuit breaker is opened manually. For manual operation, the red alarm lamp, R, is the only indication that the ground circuit breaker is open.

Under normal operating conditions with no ground except through the grounding system (contacts G closed), the main bus is energized; the ground circuit breaker contacts, CB1 and CB2 are closed and contacts CB3 are open; the ground lamp test pushbutton is in the normal (open) position; and the ground lamps, A and B, are lighted dimly.

Emergency Switchboard

The emergency switchboard for d-c systems is comparable to the a-c system discussed earlier in this chapter. The principle rules for operation are the same. The emergency switchboard on recent construction is of the dead front type, however, a large number of the older APA and AKA type ships are still equipped with the live-front switchboard for emergency power distribution.

OPERATION OF GENERATORS

The following procedures are standards as established by NavShip Systems Command for the operation of a-c or d-c generators.

Both a-c and d-c ship service generators should be inspected before starting and also before applying load to minimize the possibility of any machinery derangement that may be caused by negligent operating personnel.

Before starting a d-c generator or an a-c generator at any time (except automatically started emergency generators):

1. See that the generator circuit breaker and field switch (if furnished) are open.
2. See that the field rheostat handle is set to cut in all the field resistance.
3. Make sure that the voltage regulator control switch (if furnished) is turned to the MANUAL position.
4. Make sure that the manual voltage control is set at the position that gives the lowest generator voltage.
5. Examine both the prime mover and generator for evidence of obstruction to moving parts.
6. See that the oil reservoir for oil ring lubricated bearings contains the proper amount of oil as indicated by the oil sight gage.

Before applying load to a d-c or a-c generator at any time:

1. See that the unit is started and brought up to speed in accordance with the instructions for the type of prime mover used. Be sure that the overspeed governor and trip and all other safety devices are tested and are functioning as required by these instructions.
2. If vibration is apparent, search for possible misalignment, sprung shafting, loose foundation bolts, or something chafing the rotating elements.
3. Check lubrication of bearings; check oil and bearing temperatures.
4. See that commutator and collector rings run true, that all brushes ride freely in the brush holders, and that there is no chattering of brushes.
5. See that there is ample clearance between all rotating and stationary parts.
6. For totally enclosed machines with coolers, see that water is flowing through the cooler, as prescribed in the manufacturer's instructions and that there is no leakage of water.
7. If the generator is equipped with heaters, see that the heaters are turned off.
8. Replace covers and all cover-holding bolts if any have been removed.

NONPARALLEL OPERATION OF D-C GENERATOR

To connect a single d-c generator and/or exciter to the bus for nonparallel operation:

1. Check before starting, start, and bring the generator up to speed in accordance with the procedures for starting an idle generator.

SC311
11631

2. Close the shunt field switch and gradually cut out the field resistance until normal voltage is obtained.

3. Close the line switch (if provided).

4. Close the generator circuit breaker.

To secure a d-c generator which is connected alone to a bus:

1. Reduce the load by opening feed circuit breakers.

2. Trip the generator circuit breaker.

3. Open the line switch (if provided).

4. Secure the prime mover according to instructions.

5. Cut in all the shunt field resistance.

6. Turn on heaters (if installed).

NONPARALLEL OPERATION OF A-C GENERATOR

To connect a single a-c generator to the bus for nonparallel operation:

1. Check before starting, start, and bring the generator up to speed in accordance with the procedures for starting an idle generator.

2. Adjust the generator voltage to the rated value by the manual voltage control. Observe the generator voltmeter while manually adjusting the voltage and do not allow it to build up above its rated value. Be certain that the voltmeter indicates the voltage of the generator being regulated. Exercise care when regulating the generator because the voltage may build up high enough to damage the windings.

3. Check the frequency on the frequency meter and raise or lower the speed of the prime mover, as necessary, by means of the governor motor control switch until the normal frequency of 60 cycles is indicated. Observe the frequency meter while adjusting the frequency and be certain that the meter indicates the frequency of the generator being adjusted.

4. Place the voltage regulator in control by turning the control switch to the NORMAL or AUTOMATIC position. Check the generator voltage and, if necessary, adjust it to the desired value by means of the voltage adjusting rheostat. Normally, the voltage regulator should be placed in, and then out of, service only under steady-load or no-load conditions.

5. Turn the voltmeter switch to read the voltage on the bus. Check the bus voltage for all three phases if the connections to the voltmeter switch will permit.

6. If the bus is deenergized, turn the handle of the synchronizing switch to the ON position. The synchroscope is not needed for synchronizing because the bus is dead, but in many installations an interlock necessitates that the synchronizing switch must be in the ON position before the generator circuit breaker can be closed. Other installations are provided with an interlock defeater switch which must be passed when closing to a dead bus.

7. Close the generator circuit breaker to energize the bus and then apply load to the generator.

8. Turn the synchronizing switch to the OFF position.

To secure an a-c generator which is connected alone to a bus:

1. Reduce the load on the generator as much as practicable by opening feeder circuit breakers on the power and lighting circuits.

2. Trip the generator circuit breaker by pushing its trip button.

3. Turn the voltage regulator control switch to the MANUAL position.

4. Turn the manual voltage control as far as it will go in the DECREASE VOLTAGE direction.

Some installations require the generator to come to rest before turning the manual control to decrease voltage.

PARALLEL OPERATION OF D-C GENERATORS

If the bus is already energized and it is desired to connect another generator and/or exciter to the line:

1. Check before starting, start, and bring the generator up to speed in accordance with the procedures for starting an idle generator.

2. Close the shunt field switch (if installed).

3. Gradually cut out field resistance until the generator voltage is from 1 to 4 volts higher than the bus voltage.

4. Close the line switch (if open).

5. Close the generator circuit breaker.

6. Adjust the field rheostat to cause the generator to take its proper share of the load. Turning the field rheostat in the INCREASE VOLTAGE direction will cause a generator to take more load.

11632

To secure a d-c generator that is operating in parallel with another generator, or other generators:

1. Gradually cut in the shunt field resistance to reduce the load to a minimum.
2. Trip the generator circuit breaker.
3. Secure the prime mover in accordance with the instructions for the type of prime mover used.
4. Cut in all the shunt field resistance.
5. Turn on the heaters (if any) within the generator enclosure.
6. Shut off the flow of water through the air coolers (if any).

PARALLEL OPERATIONS OF A-C GENERATORS

On new construction "synchronizing monitors", are being used on 60 cycle ship service systems to prevent the paralleling of generators which are not synchronized. On systems using this type of monitoring it is not possible to close the circuit breaker on the incoming generator unless the phase angle, frequency and voltage are within predetermined limits as follows:

1. Phase angle between -30° and +0°.
2. Frequency difference less than .2 cycles per second.
3. Voltage difference less than 5%.

On this type of system the above conditions must be met to complete the circuit breaker closing control circuit.

Do not close the generator circuit breaker unless the incoming generator and the bus have approximately equal voltages and are in synchronism. To synchronize generators for parallel operation, proceed as follows:

1. Bring the generator up to approximately normal speed and voltage, and place the voltage regulator in control, as previously described for connecting a single generator to a dead bus.
2. Turn the voltmeter switch on the incoming generator to indicate the generator voltage on the voltmeter.
3. Turn the voltmeter switch on the adjacent generator panel to indicate the bus voltage.
4. Turn the voltage adjusting rheostat of the voltage regulator until the incoming generator voltage is equal to the bus voltage.
5. Compare the frequency of the incoming generator with that of the bus and adjust to correspond with the bus frequency.
6. Turn the synchroscope switch to the ON position. The synchroscope will rotate in one direction or the other. Adjust the speed of the generator by means of the governor motor control switch until the synchroscope rotates very slowly in the clockwise direction.
7. Be certain that the voltages of the bus and the incoming generator are still equal, and close the generator circuit breaker just before the synchroscope pointer passes very slowly through the zero position (pointing vertically upward).
8. When synchronizing lamps are used instead of the synchroscope, close the circuit breaker just before the midpoint of the dark period of the lamps is reached. The midpoint of the dark period corresponds to the vertical position of the synchroscope pointer.
9. Turn the synchronizing switch to the OFF position.

When a-c generators are operated in parallel, the kilowatt and reactive kva load should be divided between them in proportion to the generator ratings. The desired division of the kilowatt load is obtained by adjusting the governor, which controls the generator speed. To balance the reactive kva load, the generator line currents should be equal for equally rated generators and divided in proportion to generator ratings for unequally rated generators. Where power factor meters are provided, the power factors for all generators in parallel should be equal. Equality of power factor or correct division of generator line currents is obtained by adjusting the voltage-adjusting rheostats of the voltage regulators. These adjustments are made as follows:

1. Turn the governor control switches until the wattmeters have equal readings (if the generators have the same ratings) or the kilowatt load is divided in proportion to the generator ratings (if the generator ratings differ from each other).

   a. If the frequency is above normal, turn the governor control switches for the heavily loaded generators in the DECREASE SPEED direction.

   b. If the frequency is below normal, turn the governor control switches for the lightly loaded generators in the INCREASE SPEED direction.

   c. If the frequency is normal, make the adjustment in small steps, turning the governor control switches for the lightly loaded

ECP4033

generators in the INCREASE SPEED direction and for the heavily loaded generators in the DECREASE SPEED direction.

2. Turn the voltage adjusting rheostats of the voltage regulators until generator line currents are divided in proportion to generator ratings or power factor readings are equal.

a. If the voltage is above normal, turn the voltage adjusting rheostats for the generator with the highest line current, (lowest power factor) in the DECREASE VOLTAGE direction.

b. If the voltage is below normal, turn the voltage adjusting rheostats for the generator with the lowest line current (highest power factor) in the INCREASE VOLTAGE direction.

c. If the voltage is normal, make the adjustments in small steps, turning the voltage adjusting rheostats for the generators with the highest line current (low power factor) in the DECREASE VOLTAGE direction, and for the generators with the lowest line current (highest power factor) in the INCREASE VOLTAGE direction.

The reason for the procedure in step (b) above may be explained by considering two equally rated generators operating in parallel (fig. 11-29). Generator G1 (fig. 11-29) is in parallel with generator G2. The power factors are not equal; G1 has a power factor of 0.99, and G2 has a power factor of 0.67. Although both generators are assumed to have the same rating, the load current, I_1 (fig. 11-29), of G1 is smaller than the load current, I_2, of G2. Both generators supply inductive loads. The voltage, E_2', is larger than E_2 by an amount equal to E_r. Voltage E_r causes an undesirable circulating component of current I_s to flow between the two generators. Current I_s lags E_r almost 90° because of the large ratio of reactance to resistance in the local circuit between the two generators. Note that I_s lags E_2' by 90° and leads E_1 by 90°.

The circulating current, I_s, comprises a part of the total current of each generator. Thus, in G1 the total current, I_1', is made up of components I_s and I_1. Current I_1 is the current of G1 when the generator voltages are equalized, and there is no unbalanced voltage, E_r. Current I_2' is made up of components I_s and I_2. Current I_2 is the current of G2 when E_r is zero.

Equalization of the generated voltage may be obtained by lowering the field strength of G2 until E_2 is equal to E_1. For this condition I_s is reduced to zero. The current of G1 is increased from I_1' to I_1, and the current of G2 is decreased from I_2' to I_2.

The power factor of G2 is increased from cos 48° = 0.67 to cos 30° = 0.866, and the power factor of G1 is decreased from cos 1° = 0.99 to cos 30° = 0.866. Thus, if the voltage is above normal and G2 has the lower power factor, turn the voltage adjusting rheostat of G2 in the DECREASE direction. This action weakens the field of G2 and lowers its generated voltage until the circulating current is reduced to zero and the power factors are equalized.

Note that the circulating current that exists when the power factors are unequal cannot be read on either generator ammeter. However, there will always be a circulating current when the power factors are unequal, and the ammeter readings are not the same (for equal kva ratings of both generators). This current is undesirable because it causes heating and limits the output of the generator having the higher generator voltage.

To secure an a-c generator that is operating in parallel with another generator or other generators:

1. Turn the governor motor control switch of the generator being secured in the DECREASE SPEED direction and the governor motor control switch (or switches) of the other generator (or generators) in the INCREASE SPEED direction until all the load is shifted from the generator being secured. This condition can be checked by the indications on the wattmeters. If the total connected load is greater than can be carried by the generators that are to continue in operation, it will be necessary to decrease the load by opening feeder circuit breakers.

2. Trip the circuit breaker of the generator being secured.

3. Turn the voltage regulator control switch to the MANUAL position. Unless otherwise indicated in the manufacturer's technical manual, the voltage in the automatic position should be at or close to rated value prior to switching to the manual position.

4. Turn the manual voltage control as far as it will go in the DECREASE VOLTAGE direction.

OPERATION OF ELECTRIC PLANTS

The ship's electric power and lighting systems are designed to provide a high degree of

Figure 17-40.—Ground position indicator stabilization system, block diagram.

77.178

Figure 11-29.—Equalizing the power factor between generators when the voltage is above normal.

flexibility to ensure continuity of service to vital power and lighting loads under normal and casualty conditions. The distribution systems in most naval ships are arranged so that the electric plants can be operated in parallel (cross plant) or separately (split plant).

CROSS PLANT OPERATION

The setup for cross plant operation is to CLOSE all the bus ties between the ship service switchboards with the generators running in parallel so that any switchboard or several switchboards can supply electric power to any other switchboard. However, when the plant is operating CROSS PLANT, a casualty to one switchboard or load center may cause a short circuit that could trip all the generators off the line and result in temporary loss of all ship service power.

SPLIT PLANT OPERATION

The setup for split plant operation is to OPEN the bus ties between the ship service

3C3[illegible]635

switchboards so that each switchboard with its generators and loads forms a system that is independent of the others. When the plant is operating SPLIT PLANT, a casualty to one switchboard will result in loss of power for the loads fed from this switchboard but will not affect the loads fed from the other switchboards. Hence, split plant operation should be used under battle or other conditions where maximum assurance against loss of all ship service power is desired.

If auxiliaries are provided with normal and alternate power supplies, the feeder circuit breakers are CLOSED for both the normal and alternate supplies. Thus, if there is a casualty to one generator plant, power will be immediately available at the manual transfer switch for this vital equipment by means of the alternate power supply from the other generator plant. Battle loads that are not provided with alternate feeders can be supplied over the bus tie feeder if a generator casualty occurs, after isolating the damaged equipment.

CASUALTY PROCEDURES

Optimum continuity of service is ensured in ships provided with ship's service, emergency, and casualty power distribution systems. If one generating plant should fail, a remote switchboard can be connected by the bus tie to supply power from the generator or generators that have not failed.

If a circuit or switchboard fails, the vital loads can be transferred to an alternate feeder and source of ship service power by means of a transfer switch near the load.

If both the normal and alternate sources of the ship power fail because of a generator, switchboard, or feeder casualty, the vital auxiliaries can be shifted to an emergency feeder that receives power from the emergency switchboard.

If the ship's service and emergency circuits fail, temporary circuits can be rigged with the casualty power distribution system and used to supply power to vital auxiliaries if any of the ship service or emergency generators can be operated.

The casualty power system includes suitable lengths of portable cable stowed on racks throughout the ship. Permanently installed casualty power bulkhead terminals form an important part of the casualty power system. They are used for connecting the portable cables on opposite sides of bulkheads, so that power may be transmitted through compartments without loss of watertight integrity; also included are permanently installed riser terminals between decks. The vital equipment selected to receive casualty power will have a terminal box mounted on or near the equipment or panel concerned and connected in parallel with the normal feeder for the equipment.

Sources of supply for the casualty power system are provided at each ship service and emergency generator switchboard. A casualty power riser terminal is installed on the back of the switchboard or switchgear group and connected to the busses through a 225- or 250-ampere AQB circuit breaker. This circuit breaker is connected between the generator circuit breaker and the generator disconnect links so that by pulling the disconnect links the generator may be isolated from the switchboard and used exclusively for casualty power purposes, if desired.

RIGGING CASUALTY POWER

In order to eliminate the necessity of handling live cables and to reduce the hazards to personnel and equipment, there are definite procedures that must be followed and safety precautions that must be observed in rigging casualty power. Only qualified Electrician's Mates should do the actual connecting; however, the portable cables may be laid out by other repair party personnel. The repair party electrician must wear rubber goves and rubber boots, and stand on a rubber mat (if available,) while making connections. He must further test each casualty power riser or bulkhead terminal with a voltage tester before making a connection to that terminal. It is the duty of the repair party Electrician's Mate to determine that all sources of power to the equipment concerned are lost before rigging casualty power. The portable cable connections for casualty power should always be made by first connecting at the load, then working back to the source of power.

On large ships, casualty power runs will involve more than one repair party. All repair parties should rig simultaneously, but the rule of "rig from load to source" should always be observed. Each repair party must report its section rigged from riser or bulkhead terminal number to riser or bulkhead

CC311636

terminal number to damage control central, which reserves the authority to order the system energized. In making casualty power connections at a load where there are no circuit breakers or transfer switches to interrupt the incoming feeder cable, it must be disconnected or cut at the equipment. It is quite possible that this cable may be damaged by the casualty which caused the loss of power, and such a damaged cable if energized would probably trip the casualty power circuit breakers. If not disconnected, this incoming feeder cable may be reenergized, presenting a hazard to personnel handling the casualty power cables. Care should be exercised, in making all connections, to keep the phase sequence correct in a-c systems. The riser terminals, bulkhead terminals, and portable cable ends are marked to identify the A, B, and C phases either visually or by touch when illumination is insufficient for visual identification. If the load includes motors in either a-c or d-c systems, the connections should be made so as to include the motor controller in the circuit.

Ordinarily portable casualty power cables may be run along the deck. Where they form an obstruction in a passageway or working area, or where they may be subject to damage, they should be tied to the overhead. High voltage signs should be attached at each connection and the word passed over the ship's 1 MC system, informing all hands to stand clear of the casualty power cables when they are energized.

As previously stated, power panels supplying equipment designated for casualty power service will have a power terminal box mounted on the panel so that power may be fed into the panel. It is well to remember that these panels also can be used as a source of power for the casualty power system should power still be available from the permanent feeder or feeders to the panel. Some judgement should be exercised, however, in the choice of panels to be used for supplying casualty power loads. Heavy loads should be connected to power panels having large incoming feeders for greater assurance that circuit breakers will not trip and that the cable will not be overheated. For casualty power purposes, a current loading which will allow the cable to be grasped by the hand without burning is not considered excessive. Portable cable used in a-c casualty power systems is Navy THOF 42, and while the normal current carrying capacity of this cable is 43 amperes, its casualty rating is 200 amperes. Under normal conditions this cable will carry 200 amperes for 4 hours without damage to the cable. Cables may be run in parallel to circuits which overload a single cable.

Recommended SAFE procedures to be used in Rigging Casualty Power include:

1. Upon report of loss of power, damage control central orders the repair party nearest the equipment concerned to investigate.

2. The repair party Electrician's Mate in the investigating team tests immediately to determine if all sources of power to the equipment are lost.

3. Upon determining that all power is lost, the Electrician's Mate opens all supply switches to the equipment and reports all power lost to damage control central.

4. Upon receiving report of all power lost, damage control central requests main engine control to designate a source of casualty power for the equipment concerned. The request for a casualty power source may be made to the electrical officer on ships having a combined main engine control and damage control central or where the electrical officer is stationed in damage control central to control generators and power distribution.

5. Main engine control or the electrical officer as appropriate, informs damage control central of the casualty power source to be utilized (giving riser terminal number) and at the same time informs the Electrician's Mate on the appropriate switchboard that his board has been designated as a source of casualty power to the riser terminal by number.

6. Upon receiving this information, damage control central orders the repair parties concerned to rig casualty power from the equipment to the designated source.

7. Repair parties rig casualty power and report each section as completed, to damage control central.

8. When all sections have reported rigging completed, damage control central then requests the main engine control electrical officer to "energize casualty power."

11637

9. Upon receiving the request to energize, main engine control or the electrical officer directs the designated switchboard to "connect and energize casualty power," and to report compliance.

10. The Electrician's Mate on the designated switchboard rigs the first cable from the source of the system, closes the casualty power circuit breaker, and reports "casualty power energized," to main engine control or the electrical officer. Main engine control then reports compliance to damage control central.

UNRIGGING CASUALTY POWER

Unrigging casualty power can be hazardous if not handled correctly.

To unrig casualty power lines proceed as follows:

1. Damage control central requests main engine control to deenergize the casualty power system.

2. Main engine control directs the designated switchboard to "deenergize and disconnect casualty power," and to report compliance.

3. The Electrician's Mate at the switchboard opens the casualty power circuit breaker, unrigs both ends of the first portable cable, and reports "casualty power deenergized," to main engine control. Main engine control reports compliance to damage control central.

4. Upon receiving the deenergized report, damage control central then orders casualty power disconnected at the equipment.

5. The repair party Electrician's Mate then disconnects both ends of the last portable cable in the system at the load and reports, when completed, to damage control central.

6. Damage control central now requests main engine control to energize normal circuits to the equipment and orders repair parties concerned to unrig and restow the remainder of the portable cables.

7. Main engine control directs the designated switchboard to energize all normal circuits to the equipment and to report compliance. Main engine control reports compliance to damage control central. The exercise is considered completed when damage control central receives the report that the equipment is operating on normal power, and that all portable cables are restowed on their proper racks.

Speed is desirable in all casualty power operations; however, safety precautions must never be sacrificed to attain speed. A thorough knowledge of the casualty power system and frequent drills by all personnel involved are necessary for safe and expeditious results.

Casualty power systems require proper inspection and maintenance to ensure safe and dependable operation.

The insulation of casualty power cables should receive close inspection at least once a year. These cables are exposed to shipboard ambient temperatures and perhaps oil, oil fumes, and accidental damage. After an exposure period of 5 years or more, the conductor insulation may have aged and lost eleasticity to the extent that it will crack open when bent during handling incident to emergency use. The best method of detecting overage insulation of the exposed ends of individual conductors is to sharply bend each conductor by hand. If no visual cracks develop the insulation is satisfactory. If cracking is noted, the cable ends should be cut back and new terminations prepared in accordance with NavShips Technical Manual, chapter 9620, section I.

The casualty power cables should be checked after any repairs to ensure they are still of sufficient length to make proper connections to designated risers and equipments.

During the annual inspection of the portable casualty power cables, all risers and terminals should be checked and cleaned of all foreign matter.

Numerous damage control charts and diagrams that are very helpful to damage control personnel are prepared for all ships. Among these charts and diagrams there should be a casualty power supply and emergency communication system chart for your ship. This chart will show the ship's casualty power and emergency communication systems in detail. Another chart that should be available to all personnel concerned with electrical damage control is one for vital damage control electrical equipment and power supply. This chart supersedes the electric wiring table that was included in damage control diagrams and charts at the end of World War II. Figure 11-30 shows a portion of a vital damage control electrical equipment chart for a representative ship. These charts and diagrams are usually prepared by the building activity when a ship is built, however, extra copies

are available upon request to Naval Ship Systems Command.

MAINTENANCE

The purpose of maintenance is to ensure that the equipment is ready for service at all times. Three fundamental rules for the maintenance of electrical equipment are: (1) keep equipment clean and dry, (2) keep electrical connections and mechanical fastenings tight, and (3) inspect and test at sufficiently short intervals to ensure that the equipment is in operating condition.

Chapter 6 of this course discussed maintenance of motors and generators. For additional information read chapters 9600 and 9610 of the NavShips Technical Manual.

GENERATORS

In chapter 6 of this course a typical Maintenance Requirement Card for weekly maintenance of an emergency generator was shown. Figure 11-31 is a Maintenance Requirement Card for a ship service generator; it covers the monthly required maintenance. Since all ships do not as yet have the 3-M System in effect, they will follow the instructions of the NavShips Technical Manual. Section 1 of chapter 9620 of NavShips Technical Manual gives additional coverage on power distribution systems.

Generator maintenance is directed primarily to keeping the electrical insulation in good condition. It must be clean, dry, and of high resistance.

111639

SYSTEM	COMPONENT	M.R. NUMBER
Electric Plant	Ship Service Generator	EL-7 M-1
SUB-SYSTEM: Electric Power Generation	RELATED M.R.: None	RATES: EM3 — M/H: 0.3

M.R. DESCRIPTION
1. Inspect each idle ship service generator for evidence of corrosion and electrolytic action (exciter where applicable).

TOTAL M/H: 0.3
ELAPSED TIME: 0.3 unit

SAFETY PRECAUTIONS
1. Observe standard safety precautions.
2. Tag generator throttle valve "Brushes Raised, Do Not Operate."

(Cont'd on Page 2)

TOOLS, PARTS, MATERIALS, TEST EQUIPMENT
1. 6" Adjustable wrench
2. 8" Screwdriver
3. Flashlight
4. Safety tags

PROCEDURE

Preliminary
a. Tag generator throttle valve "Brushes Raised, Do Not Operate."
b. Open generator disconnect links on main switchboard and tag "Out Of Service."
c. Ensure generator circuit breaker is open.

NOTE 1: If a generator is allowed to stand secured for extended periods, an electrolytic action may take place between the brushes and slip rings, causing a rough imprint of the brushes on the rings. The area of the slip rings under the brushes may corrode.

NOTE 2: When it is known the generator will be idle for a period of one month or longer, all brushes should be raised and set on paper.

1. Inspect Each Idle Ship Service Generator for Evidence of Corrosion and Electrolytic Action (exciter where applicable).

(Cont'd on Page 2)

LOCATION

Page 1 of 2 | EA | ZZZG | GG1 | 84 | 6012 | M

Safety Precautions (Cont'd)
3. Open generator disconnect links on main switchboard and tag "Out Of Service."
4. Ensure circuit breaker is open and tagged "Out Of Service."
5. De-energize stator space heater where installed.

Procedure (Cont'd)
a. Remove the inspection cover or screen and inspect the commutating surface for evidence of corrosion, a light verdigris.
b. Lift each brush and inspect the area covered by the brush for electrolytic action: abnormal discoloration, roughness, or pitting.
c. If abnormally discolored, rough, or corroded, corrective action must be taken.
d. Close generator disconnect links and remove tags.

Figure 11-31.—Monthly MRC for ship service generator. 98.176

The insulation resistance of each ship service, emergency, and exciter generator should be measured weekly or when securing and the results recorded on the Resistance Test Record card, NavShips 531. The armature and field should be measured separately on all generators except d-c generator having an internally connected shunt field. When measuring d-c armatures and a-c revolving fields, make the ground connection to a metallic part of the rotor to eliminate the insulating effect of the bearings. Normally the insulation resistance is measured immediately after a generator is shut down. Periodic measurements on idle generators will detect any moisture absorption in the windings.

MICROCOPY RESOLUTION TEST CHART
NATIONAL BUREAU OF STANDARDS-1963-A

Portable electric lights (with guard) may be placed inside idle generators not provided with space heaters to keep the insulation dry. Only enough heat to keep the temperature inside the generator, about 5° to 10° above ambient temperature is required.

Taking air gap readings on ship service and emergency generators, and other information concerning generator maintenance appears in chapter 6 of this training course.

SWITCHBOARDS

Numerous derangements of electrical equipment have been caused by loose electrical connections or mechanical fastenings. Loose connections can be readily tightened, but a thorough inspection is necessary to detect them.

Inspection

At least once a year and during each overhaul, each switchboard propulsion control cubicle, distribution panel, and motor controller should be deenergized for a complete inspection and cleaning of all bus work equipment. The inspection of deenergized equipment should not be limited to visual examination but should include grasping and shaking electrical connections and mechanical parts to be certain that all connections are tight and that mechanical parts are free to function. Be certain that no loose tools or other extraneous articles are left in or around switchboards and distribution panels.

Check the supports of bus work and be certain that the supports will prevent contact between bus bars of opposite polarity or contact between bus bars and grounded parts during periods of shock. Clean the bus work and the creepage surfaces of insulating materials, and be certain that creepage distances (across which leakage currents can flow) are ample. Check the condition of control wiring and replace if necessary.

Be certain that the ventilation of rheostats and resistors is not obstructed. Replace broken or burned out resistors. Temporary repairs can be made by bridging burned out sections when replacements are not available. Apply a light coat of petrolatum to the face plate contacts of rheostats to reduce friction and wear. Be certain that no petrolatum is left in the spaces between the contact buttons as this may cause burning and arcing. Check all electrical connections for tightness and wiring for frayed or broken leads. Service commutators and brushes of potentiometer-type rheostats in accordance with the instructions for d-c machines.

The pointer of each switchboard instrument should read zero when the instrument is disconnected from the circuit. The pointer may be brought to zero by external screwdriver adjustment. Caution: This should not be done unless proper authorization is given. Repairs to the switchboard instruments should be made only by the manufacturers, shore-repair activities, or tenders.

Be certain that fuses are the right size; clips make firm contact with the fuses; lock-in devices (if provided) are properly fitted; and that all connections in the wiring to the fuses are tight.

In addition to the foregoing inspections, switchboards and distribution panels should be deenergized after firing, if practicable, and thoroughly inspected for tightness of electrical connections and mechanical fastenings. Emergency switchboards should be tested regularly in accordance with the instructions furnished with the switchboard in order to check the operation of the automatic bus transfer equipment and the automatic starting of the emergency generator. This test should be made in connection with the weekly operating test of emergency generators.

Control Circuits

Control circuits should be checked to ensure circuit continuity and proper relay and contactor operation. Because of the numerous types of control circuits installed in naval ships, it is impracticable to set up any definite operating test procedures in this training course. In general, certain control circuits, such as those for the starting of motors or motor-generator sets, or voltmeter switching circuits, are best tested by using the circuits as they are intended to operate under service conditions.

Protective circuits, such as overcurrent, reverse power, or reverse current circuits, usually cannot be tested by actual operation because of the danger involved to the equipment. These circuits should be visually checked, and, when possible, relays should be operated manually to be certain that the rest

116 [illegible]011

of the protective circuit performs its intended functions. Exercise extreme care not to disrupt vital power service or to damage electrical equipment.

Cleaning

Bus bars and insulating materials can usually be cleaned sufficiently by wiping with a dry cloth. A vacuum cleaner, if available, can also be used to advantage. Be certain that the switchboard or distribution panel is completely dead and will remain so until the work is completed; avoid cleaning live parts because of the danger to personnel and equipment.

Use a dry cloth, not soap and water, on the front panels of live-front switchboards or on other panels of insulating material. The front panels of dead-front switchboards can be cleaned without deenergizing the switchboard. These panels can usually be cleaned by wiping with a dry cloth. However, a damp, soapy cloth can be used to remove grease and fingerprints. Then wipe the surface with a cloth dampened in clear water to remove all soap and dry with a clean, dry cloth. Cleaning cloths must be wrung out thoroughly so that no water runs down the panel. Clean a small section at a time and then wipe dry.

BUS TRANSFER EQUIPMENT

Bus transfer equipment should be tested weekly. For manual bus transfer equipment, manually transfer a load from one power source to another and check the mechanical operation and mechanical interlocks. For automatic bus transfer equipment, check the operation by means of the control push-switches. The test should include operation initiated by cutting off power (opening a feeder circuit breaker) to ascertain if an automatic transfer occurs.

OPERATING RULES

There are a few simple operating rules which should be observed on all installations; these are:

Watch the switchboard instruments. They show how the system is operating, reveal overloads, improper division of kilowatt load or of reactive current between generators operating in parallel, and other abnormal operating conditions.

Keep the frequency (on a-c systems) and voltage at their correct values. Departure from either affects, to some extent at least, the operation of all equipment supplied with electric power. Low or high voltage has a particularly pronounced effect on lights since low voltage results in a marked decrease in illumination, while high voltages materially shorten lamp life. The operation of vital electronic, interior communication, and fire control equipment is also seriously affected. This sensitive equipment requires careful adjustment of voltage regulators and prime mover governors to obtain satisfactory performance.

Use judgment when reclosing circuit breakers after they have tripped automatically. If a circuit breaker trips immediately upon the first reclosure, it is desirable to investigate before again reclosing. The circuit breaker may, however, be closed a second time without investigation if the immediate restoration of power to the circuit is important and the interrupting disturbance when the breaker tripped was not excessive. It should, however, be kept in mind that repeated closing and tripping may result in damage to the circuit breaker and, hence, may increase the repair or replacement work needed to get the circuit back in operation again.

Use the hold-in device on circuit breakers with judgment and only when necessary. The hold-in device enables an operator to hold a trip free circuit breaker closed when the current is in excess of the tripping value. The circuit breaker will open automatically as soon as the hold-in device is released if the current is above the tripping current. In an emergency it may be vitally important to obtain power even at the risk of burning out equipment. The hold-in device makes it possible to do this. However, when holding a circuit breaker closed, it must be kept in mind that the circuit is deprived of protection against damage by excessive current and the longer the circuit breaker is held closed, the greater is the change of permanent damage to circuits or equipment.

A circuit breaker should never be held closed unless there is an emergency which justifies the risk.

Never parallel ship service generators until they have been brought into synchronism.

116[illegible]11

Never close the bus tie circuit breakers to parallel the buses on two energized switchboards until the buses have been brought into synchronism.

Never close the bus tie circuit breaker to restore power to a switchboard which has lost power because of failure of a local generator that was supplying power to the switchboard prior to the generator failure, unless the generator circuit breaker has first been tripped by hand, or unless it has been definitely established that the generator circuit breaker is in the open position.

Never parallel ship service generators with shore power except for the short interval required to transfer the load from one source of power to the other. Never parallel ship service generators with shore power of a different frequency such as 50 cps. Never parallel with shore power without the use of synchroscope or synchronizing lights. On ships where a synchroscope is not provided for synchronizing between shore power and the bus, the generator breakers shall be opened first and then the shore power breaker shall be closed. On some ships, shore power may be connected to the bus tie with the bus tie breakers open and synchronizing can be accomplished across the bus tie breakers. When placing the shore power and the ships service generators in parallel, the normal synchronizing process is reversed. The incoming shore power is the controlling source and the voltage and frequency of the ship service generators must be made to match the shore power voltage and frequency. There are several precautions to be taken when paralleling with shore power in addition to the usual ones when paralleling two ship's service generators. The shore power connection phase rotation must be the same as the ship phase rotation. If there is to be more than one shore power connection and they are to be paralleled, the actual phases of the shore power should not only be in the same rotation but must be connected to match the ship's phases in order to avoid a short circuit through the ship's system. When paralleling with shore power for purposes of transfering the load, bring the ship's voltage up to the shore power voltage or as close thereto as possible. In some cases, the shore power voltage may be around 480 volts.

Increase the ship's generator to 480 volts. Now bring the ship's frequency to that of the shore power. Turn on the synchroscope, synchronize the ship's power with the shore power, and close the shore power breaker. Quickly transfer load to the shore power. Trip the ship service generator breakers.

Never parallel an emergency generator with any other generator except on certain ships where the emergency generator also serves as a "standby set" and, as such, provisions have been made for paralleling with the ship service power system.

Always check phase sequence before making connection to a shore power supply and be sure to make connections so that the phase sequence on the shore power will be A, B, C. If the shore power connection is made so that it gives the wrong phase sequence on the ship, motors will run in the wrong direction.

Always observe electrical safety precautions. Never adjust a ventilation opening for personal comfort of watchstanders to a position where spray or solid water entering the system through weather openings can be discharged onto switchboards, distribution panels, bus bars, or other electrical equipment.

Always operate switchboards and distribution system equipment as if no automatic protective devices were installed. Trouble will sooner or later be the inevitable consequence of careless and slipshod operating practices based upon the assumption that automatic protective devices either will prevent incorrect operation or will prevent damage from incorrect operation. They will not because they are not designed or intended to do this. The protective devices used with the distribution system are intended to afford protection against damage as a consequence of equipment failure, not of operator failure. The intelligence which is needed for the operation of the distribution system is not built into the system but must be furnished by the operator. You must, therefore, read and follow the instructions on warning plates and indicator lights, must know the system and operate it correctly, and must never depend upon automatic devices to keep you from making a mistake or to save you from the consequences of a mistake.

11343

readings. The N/S summing network receives the cosine outputs from the heading and wind channels. The E/W summing network receives the sine outputs. In the N/S summing network, the N/S components of airspeed and wind are combined, and the result is an output voltage equivalent to the N/S groundspeed of the aircraft. Similarly, the E/W summing network has an output voltage equal to the E/W speed of the aircraft. The N/S and E/W channels are identical from this point on.

After groundspeed has been determined, adding the factor of time is the only remaining factor in order to compute distance. This is done in the ground track channels, and both channels operate in exactly the same manner with their respective voltage inputs.

Ground Track Channel

The ground track channel converts the component of groundspeed into distance by taking into account the length of time the aircraft travels at the groundspeed. This is done by a motor-driven tachometer (or rate generator) which rotates at a speed proportional to the groundspeed of the aircraft. This rotation is in a direction corresponding to the direction of travel. A ground track synchro, coupled to the motor-generator, provides output data at 2 miles per revolution.

Distance Channel

The distance channels convert the rotation of the ground track synchros into distance counter information. By using synchros and servomotors, the information is transferred through a gearing mechanism that causes the stabilization potentiometers to provide the proper voltages to the radar sweep deflection system. These voltages (from the N/S and E/W stabilization pots) will ground stabilize the display so that the radar continues to view the area selected. The distance channel also positions the dials of the Veeder-root counter to indicate the distances traveled. Some computers will ground stabilize a sweep up to 300 miles. Beyond this range, resetting is required, resulting in the PPI origin being moved to a new position.

RADAR SECTION

The computer section is an auxiliary unit that works in conjunction with the radar set and the remaining GPI circuitry is self contained within the radar set.

The internal slewing circuits are identical for both manual and automatic operation. The amount of slew available for manual slew is 50 miles maximum in any one quadrant, and for automatic slew is 150 miles maximum in any one quadrant.

The manual slew helipots are located on the control box. Only N/S circuitry is discussed because the E/W circuitry is identical. Figure 17-41 is a simplified schematic and presents only that portion of the circuitry that pertains to the slewing function.

The synchronizer provides the circuitry necessary to convert the input voltages into the push-pull d-c output voltages necessary for slew indications. This conversion is accomplished by the following four main stages:

1. Input limiters—which provide the safety factor for the input cathode followers and d-c amplifiers.
2. Input cathode followers—which isolate the input circuits from the d-c amplifiers.
3. D-c amplifiers—which are used in conjunction with their degenerative feedback loop to control the gain.
4. Output cathode followers—which are used to isolate the d-c amplifiers from the indicator circuits and to provide degenerative feedback for the amplifiers.

In the indicator section, the sweep voltages are combined with the slew voltages. The clampers in the indicator section are controlled by the sweep and slew voltages and in turn provide the proper bias for the sweep drivers. The drivers provide the proper sweep currents for the deflection coils.

Circuit Analysis

In order to determine the position of the origin of the sweep on the indicator, the bias on the sweep drivers must be controlled. When it is desired that the sweep origin be in the center of the indicator, all four drivers are held at -19 volts d-c grid bias. Whenever slew is desired, this bias is changed in a push-pull manner in the direction desired. Helipots (R1 and R2) provide the manual slew input for the N/S channels. A maximum of 50 volts push-pull may be obtained from the two ganged controls. One volt, at this point, provides 1 mile of slew (displacement) on the indicator.

1162

CHAPTER 12

ELECTRIC AUXILIARIES

Electrician's Mates 3 and 2 are required to man electrical equipment in the steering gear room, anchor windlass room, at the degaussing switchboard, and at electric elevator and hoist stations. They are also required to service electric galley equipment and appliances by taking resistance and current measurements, cleaning switches and relays, replacing defective heating units, thermostats, and control or unit wiring.

The purpose of this chapter is to explain the operating principles of these electric auxiliaries and to describe the proper methods and procedures for maintaining this equipment.

DEGAUSSING INSTALLATIONS

The German development and use of magnetic mines initiated the development of degaussing systems. In September 1939, the Germans began laying magnetic mines in shipping lanes off the east coast of England. Within three months 44 ships were sunk by these mines. Thus the British Admiralty made the development of countermeasures a problem of highest priority. The magnetic mine outdated with one blow the countermine and sweeping techniques developed in World War I.

The United States was quick to recognize the threat presented by magnetic mines in the hands of a potential enemy. On December 6, 1939 the Bureau of Ordnance (now Ordnance System Command) met with experts to consider the related problems of sweeping magnetic mines and building some sort of defensive mechanism into the hulls of mine sweepers. Since that meeting there has been continual and ever increasing improvements of equipments for countering magnetic mines and torpedoes.

The detonation of a magnetic mine or torpedo depends on a localized disturbance or distortion of the earth's magnetic field. This distortion is caused by a ship passing over or near the mine or torpedo. The purpose of the degaussing installation is to reduce the magnitude of the distortion caused by the ship, and thus minimize the danger of firing the magnetic mine or torpedo.

A ship is a magnet because of the presence of magnetic material in its hull, machinery, and other equipment. Therefore it is surrounded by a magnetic field, which is large near the ship and small at a considerable distance from the ship. The earth's magnetic field is uniform at any particular point on the surface of the earth. When a ship passes over a point on the earth's surface, the ship's magnetic field is superimposed on the earth's magnetic field, thus tending to distort the earth's field around the ship. If the ship is close to a magnetic mine or torpedo, the distortion caused by the ship's field will activate the firing mechanism to detonate the mine or torpedo.

Degaussing equipment is installed aboard ship to neutralize the disturbance of the earth's magnetic field caused by the ship and thus to reduce the possibility of detonating a magnetic mine or torpedo. A shipboard degaussing installation consists of one or more coils of electric cable in specific locations inside the ship's hull, a d-c power source to energize these coils, and a means of controlling the magnitude and polarity of the current through the coils. Compass-compensating equipment, consisting of compensating coils and control boxes, is also installed as a part of the degaussing system to compensate for the deviation effect of the degaussing coils on the ship's magnetic compasses.

EARTH'S MAGNETIC FIELD

Figure 12-1 shows the earth as a sphere with imaginary lines of force leaving the north magnetic pole and entering the south magnetic pole. The south magnetic pole is near the north

11644

27.104

Figure 12-1.—Earth's magnetic field.

geographic pole and the north magnetic pole is near the south geographic pole. The apparent contradiction is clarified by the imaginary bar magnet in (fig. 12-1) whose axis lies approximately along the earth's axis of rotation and whose poles are by definition north near the earth's geographic south pole and south near the earth's geographic north pole.

The magnetic field is strong where the lines of force are close together (near the magnetic poles) and weak where they are far apart (away from the magnetic poles). The lines of force in the earth's magnetic field extend vertically outward at the north magnetic pole, vertically inward at the south magnetic pole, horizontally midway between the magnetic poles, and at varying angles at all other points.

The unit of magnetic flux density is the gauss, and the unit of magnetic field intensity is the oersted. The relation between the gauss and oersted is expressed by the equation.

$$B = \mu \underline{H}$$

where $\underline{B}$ is the magnetic flux density in gausses, $\underline{H}$ the magnetic field intensity in oersteds, and μ the permeability of the surrounding media. For all practical purposes with respect to degaussing, the permeability μ, is taken as 1, and the magnetic field strength (intensity) $\underline{H}$, is measured in terms of the gauss (rather than oersteds), which is incorrect but does not lead to serious misunderstanding in degaussing terminology. One milligauss is one-thousandth of a gauss. At any point on the earth's surface the earth's magnetic field can be resolved into a horizontal component and a vertical component.

Horizontal Component

The horizontal component (also designated by the symbol, $\underline{H}$) of the earth's magnetic field is always directed from south to north, is zero at the magnetic poles, and is maximum at the magnetic equator.

Vertical Component

The vertical component ($\underline{Z}$) of the earth's magnetic field is directed radially outward (upward) south of the magnetic equator, is directed radially inward (downward) north of the magnetic equator, is zero at the magnetic equator, and is maximum at the magnetic poles.

The angle at which the flux lines strike the earth's surface (horizontal) depends on the magnetic latitude. Hence, for a given total field strength, the magnitudes of the horizontal and vertical components depend on the angle that the field makes with the horizontal. For example, the horizontal and vertical components of the earth's magnetic field at point A (fig. 12-13) are $\underline{H} = \underline{R} \cos \theta$ and $\underline{Z} = \underline{R} \sin \theta$ respectively, where $\underline{H}$ is the horizontal component, $\underline{Z}$ the vertical component, $\underline{R}$ the total earth's field, and θ the angle at which the flux lines strike the earth's surface.

SHIP'S MAGNETIC FIELD

The magnetic field of a ship is the resultant of the algebraic sum of the ship's permanent magnetization and the ship's induced magnetization. The ship's magnetic field may have any angle with respect to the horizontal axis of the ship, and any magnitude.

Permanent Magnetization

The process of building a ship in the presence of the earth's magnetic field develops a certain amount of permanent magnetism in the ship. The magnitude of the permanent magnetization depends on the earth's magnetic field at the place where the ship was built, the material of which the ship is constructed, and the orientation of the ship at time of building with respect to the earth's field. This magnetization after construction is independent of the varying or immediate earth's magnetic field, the heading, and the roll and pitch of the ship. The permanent magnetism of a ship may vary over long periods of time.

The ship's permanent magnetization can be resolved into the (1) vertical permanent field component and (2) horizontal permanent field component. The horizontal permanent field component comprises the longitudinal permanent field component and athwartship permanent field component. The vertical, longitudinal, and athwartship permanent field components are constant, except for slow changes with time, and are not affected by changes in heading or magnetic latitude.

All ships that are to be fitted with a shipboard degaussing installation and some ships that do not require degaussing installations are depermed. Deperming is essentially a large scale version of demagnetizing a watch. The purpose is to reduce permanent magnetization and bring all ships of the same class into a standard condition so that the permanent magnetization, which remains after deperming, is approximately the same for all ships of the class.

Induced Magnetization

After a ship is built, its very existence in the earth's magnetic field causes a certain amount of magnetism to be induced in it. The ship's induced magnetization depends on the strength of the earth's magnetic field and on the heading of the ship with respect to the inducing (earth's) field.

The ship's induced magnetization, similar to the ship's permanent magnetization, can be resolved into the (1) vertical induced field component and (2) horizontal induced field component. The horizontal induced field component also comprises the longitudinal induced field component and athwartship induced field component.

The magnitude of vertical induced magnetization depends on the magnetic latitude. The vertical induced magnetization is maximum at the magnetic poles and zero at the magnetic equator. The vertical induced magnetization is directed down when the ship is north of the magnetic equator and up when the ship is south of the magnetic equator. Hence, the vertical induced magnetization changes with magnetic latitude, and to some extent, when the ship rolls or pitches. The vertical induced magnetization does not change with heading because a change of heading does not change the orientation of the ship with respect to the vertical component of the earth's magnetic field.

The longitudinal induced magnetization changes when either the magnetic latitude or the heading changes, and when the ship pitches. If a ship is headed north geographic, the horizonal component of the earth's magnetic field induces a north pole in the bow and a south pole in the stern (fig. 12-2). In other words, the horizontal component of the earth's field induces a longitudinal or fore-and-aft component of magnetization. The stronger the horizontal component of the earth's magnetic field, the greater will be the longitudinal component of magnetization. If the ship starts at the south magnetic pole and steams toward the north magnetic pole the longitudinal component of induced magnetization starts at zero at the "south" magnetic pole, increases to a maximum at the magnetic equator, and decreases to zero at the "north" magnetic pole. Hence, for a constant heading the longitudinal component of induced magnetization changes when the ship moves to a position where the horizontal component of the earth's magnetic field is different—that is, when the ship changes its magnetic latitude.

If at a given magnetic latitude the ship changes heading from north to east, the longitudinal component of induced magnetization changes from a maximum on the north heading to zero on the east heading. When the ship changes heading from east to south, the longitudinal component increases from zero on the east heading to a maximum on the south heading. On southerly headings a north pole is induced at

11646

27.105
Figure 12-2.—Horizontal component of earth's field induces longitudinal magnetization in the ship.

27.106
Figure 12-3.—Athwartship component of earth's field induces athwartship magnetization in the ship.

the stern and a south pole at the bow, which is a reversal of the conditions on northerly headings when a north pole is induced at the bow and a south pole at the stern. The longitudinal component of induced magnetization also changes, to some extent, as the ship pitches.

The athwartship induced magnetization changes when either the magnetic latitude or the heading changes, and when the ship rolls or pitches. When a ship is on an east heading, a north pole is induced on the port side and a south pole on the starboard side (fig. 12-3), which is the athwartship component of induced magnetization. The magnitude of the athwartship magnetization depends on the strength of the horizontal component of the earth's magnetic field at that latitude. This component is maximum at the magnetic equator and zero at the magnetic poles.

The athwartship component of induced magnetization also changes when the ship's heading changes. The magnitude of the athwartship component of induced magnetization is maximum when the ship is headed magnetic east or west, and zero when the ship is headed magnetic north or south. The athwartship component of induced magnetization also changes, to some extent, as the ship rolls or pitches.

MAGNETIC RANGES AND RANGING

A magnetic range is a station equipped to measure the magnetic field of ships which pass over measuring equipment located at or near the bottom of the channel in which the ships travel. The magnetic range is more commonly called a Degaussing Range or Degaussing Station. The number of degaussing stations in operation has varied from time to time but the Navy at one time had seventy-five degaussing stations at various locations throughout the world.

A ship is said to be "ranged" when its magnetic field is measured at a magnetic range. Ranging has two classifications; calibration ranging and check ranging.

Calibration Ranging

Calibration ranging provides information for degaussing charts, determines initial degaussing coil current and indicates if changes or modifications are required to the ship's degaussing installation.

Check Ranging

Check ranging determines the adequacy of current settings and the performance of degaussing equipment and personnel.

For accurate ranging the ship must pass directly over the range at a constant speed and heading. The degaussing coils must be set

11647

correctly in accordance with the values given in the degaussing folder. The range officer must be notified of coil settings and of the ship's draft, forward and aft, to the nearest six inches, for depth correction. Check ranging should be run at every opportunity and at least once a year. Degaussing ranges are generally situated to allow check ranging of ships as they pass in and out of port in the course of normal operations.

Some degaussing stations use coils installed temporarily to provide a magnetic treatment which furnishes some measure of protection against magnetic mines. Degaussing by magnetic treatment does not, however, protect against magnetic mines as effectively as a shipboard degaussing installation.

DEGAUSSING COILS

As stated previously, the ship's permanent magnetization can be resolved into the (1) vertical permanent magnetization, (2) longitudinal permanent magnetization, and (3) athwartship permanent magnetization components. Similary, the ship's induced magnetization can be resolved into the (1) vertical induced magnetization, (2) longitudinal induced magnetization, and (3) athwartship induced magnetization components. Each of the six components of the ship's magnetization produces a magnetic field in the vicinity of the ship.

The distortion of the earth's field caused by the superimposing of the six components of the ship's field is neutralized by means of degaussing coils. The degaussing coils are made with either single-conductor or multiconductor cables. Coils with single-conductor cables have only one turn or a small number of turns. Single-conductor coils or a combination of some single-conductor and some multiconductor coils are usually specified for large vessels. Coils with multiconductor cables have the conductors in one or more cables connected in series to give a considerable number of turns. Multiconductor coils are usually specified for the smaller ships. The coils must be energized by direct current, which is supplied from 120-volt or 240-volt, d-c ship's service generators or from degaussing power supply equipment installed for the specific purpose of energizing the degaussing coils.

The degaussing coils consist of coils of cable wound on the ship, each having the required location and the number of turns to establish the required magnetic field strength when energized by direct current of the proper value and polarity. The coils will then produce magnetic field components equal and opposite to the components of the ship's field. Each coil consists of the main loop and may have smaller loops within the area covered by the main loop, usually at the same level. The smaller loops oppose localized peaks that occur in the ship's magnetic field within the area covered by the main loop. The resultant effect of the degaussing coils when the currents are properly set is to restore the earth's field to the undistorted condition around the ship.

The various components of the ship's magnetic field are compensated by means of standardized arrangements and combinations of degaussing coils. A degaussing installation consists of one or more of these degaussing coils, depending on the degree of safety required for the particular ship (fig. 12-4).

M Coil

The M or main coil (fig. 12-4.A) encircles the ship in a horizontal plane, which is usually at the waterline. The function of the M coil is to produce a magnetic field, which counteracts the magnetic field produced by the vertical permanent and the vertical induced magnetization of the ship. If the M coil field were everywhere exactly equal and opposite to the field produced by the vertical magnetization, the resultant of the two magnetic fields everywhere would be equal to zero. In practice, it is not possible to attain a perfect match, but the resultant is much less than the field produced by the vertical magnetization of the ship.

The permanent vertical magnetization of a ship is constant, but the vertical induced magnetization varies with the magnetic latitude and with the roll and pitch of the ship, but not with the heading. The resultant of the permanent and induced vertical magnetization will also vary with the magnetic latitude and with the roll and pitch of the ship. Hence, the M coil current must be changed when the ship changes magnetic latitude in order to keep the M coil field as nearly as possible equal and opposite to the field produced by the ship's vertical magnetization. The change in vertical magnetization caused by roll and pitch of the ship is relatively small, and only in special cases is it necessary to compensate for this change.

F and Q Coils

The F or forecastle coil encircles the forward one-fourth to one-third of the ship and is

11048

27.107

Figure 12-4.—Types of degaussing coils.

usually just below the forecastle or other uppermost deck; whereas, the Q or quarterdeck coil encircles the after one-fourth to one-third of the ship and is usually just below the quarterdeck or other uppermost deck (fig. 12-4.B). The function of the F and Q coils is to counteract the magnetic field produced by the ship's longitudinal permanent and longitudinal induced magnetization. The resultant F and Q coil strengths are then equal to the algebraic sums of their permanent and induced current requirements. The shape of the magnetic field produced by the F and Q coils is somewhat different from the magnetic field produced by the ship's longitudinal magnetism, but the two fields are, in general, oppositely directed below the bow and stern of the ship. The F and Q coils are not used to compensate for changes in the magnetic field resulting from the pitch of the ship.

The ship's longitudinal permanent magnetization is constant but the longitudinal induced magnetization changes with the heading and magnetic latitude. Therefore, the F and Q coil currents must be changed when the ship changes its course or magnetic latitude in order to keep the coil strengths at the proper values to counteract the changes in the ship's longitudinal induced magnetization. Two adjustments are necessary, one to change the F coil current and one to change the Q coil current. In many installations the conductors of the F and Q coils are connected to form two separate circuits designated as the FI-QI coil and the FP-QP coil (fig. 12-4.B).

The FI-QI coil consists of an FI coil connected in series with a QI coil so that the same current flows in both coils. The FP-QP coil is similarly connected.

The FI-QI coil is used to counteract the magnetic field produced by the ship's longitudinal induced magnetization. The longitudinal induced magnetization changes when the ship changes heading or magnetic latitude, and the FI-QI coil current must be changed accordingly.

The FP-QP coil is used to counteract the magnetic field produced by the ship's longitudinal permanent magnetization. The longitudinal permanent magnetization does not change when the ship changes heading or magnetic latitude, and no change is needed in the strength of the FP-QP coil. In contrast to the F and Q coils, the FI-QI and FP-QP coil currents require only one adjustment, instead of two when the ship changes heading or magnetic latitude.

L Coil

The L or longitudinal coil (fig. 12-4) consists of loops in vertical planes that are parallel to the frames of the ship. The function of the L coil is to counteract the magnetic field produced by the ship's longitudinal permanent and longitudinal induced magnetization. The L coil is more difficult to install than the F and Q coils or FI-QI and FP-QP coils, but provides better neutralization because it more closely simulates the longitudinal magnetization of the ship. The L coil is often used in minesweeper vessels.

The longitudinal induced magnetization changes when the ship changes heading or magnetic latitude, and the L coil current must be changed accordingly. When compensation for pitch is required, the L coil current must also be changed as the vessel pitches.

0201849

is illustrated in figure 12-5. A detailed description of the marking for degaussing-coil loops, circuits, conductors, and cables and for degaussing feeder cable and feeder-cable conductors is contained in Chapter 9810, Section III of the NavShips Technical Manual.

Connection And Through Boxes

Connection and through boxes are similarly constructed watertight boxes, but they are used for different purposes (fig. 12-5).

A CONNECTION BOX is a watertight box with a removable cover used to connect loops together to connect conductors in series, and to reverse turns. The power supply connection for a coil and all adjustments of ampere-turn ratios between loops are made within connection boxes. The power supply cable and interconnecting cable for the FI-QI and FP-QP coils terminate in connection boxes. The marking of the conductors in the single-loop M coil connection box (Box D5 of fig. 12-5) is illustrated in figure 12-6.

A THROUGH BOX is a watertight box with a removable cover used to connect conductors without changing the order of conductor connections. Also, a through box is used when it is necessary to connect sections of cable. In some cases splicing in lieu of through boxes is used.

Connection and through boxes in the M, MX, F, Q, FI-QI, and FP-QP coils are considered to be in one group. They are NUMBERED D1, D2, D3, etc., in sequence, starting at the bow and going around the ship in a counterclockwise direction when viewed from above (fig. 12-5).

Boxes for the A coil have the next higher numbers after the numbering of the M, F, FI, FP, QI, and QP boxes. The A coil boxes are numbered in sequence, starting with the highest forward box and continuing aft on the upper limbs of both the A1 and A2 loops, then down to and forward on the lower limbs, and then up (fig. 12-5).

Boxes for the L coil have the next higher numbers after the numbering of the A coil boxes. The L coil boxes are numbered in sequence, starting with the highest forward box on the port side and continuing around the vessel in a counterclockwise direction when viewed from above. Boxes on the centerline are considered to be on the port side for the assignment of numbers.

Connection and through boxes are provided with IDENTIFICATION PLATES that include:

1. Degaussing box numbers (D1, D2, D3, etc.).
2. Connection box and/or through box as applicable.
3. Coil and loop designations (M1, M2, F12, Q12, etc.).

For example,

	D1	
Connection Box		Through Box
M1		F1
M2		

identifies the No. 1 degaussing box serving as a connection box for the M1 and M2 loops and as a through box for the F1 loop.

A wiring diagram of the connections in the box is pasted on the inside of the cover and coated with varnish or shellac. The wiring diagram for connection boxes should (1) designate the conductors that may be reversed without reversing the other loops, (2) indicate the arrangement of parallel circuits so that equal changes can be made in all parallel circuits when such changes are required, and (3) show the spare conductors. Spare conductors should be secured to connectors and should be connected to form a closed or continuous circuit. All conductors in a connection box should be 1-1/2 times the length required to reach any terminal within the box. Connection boxes should also be fitted with drain plugs to provide accessibility for periodic removal of accumulated moisture from the boxes.

COIL-CURRENT CONTROL

Degaussing installations, as previously stated, consist of different combinations of degaussing coils and manual or automatic degaussing equipment for control of the current in these coils. The selected combination depends on the size and the intended use of the particular ship.

The currents in the degaussing coils must be changed when there are changes in the ship's heading, magnetic latitude, or both. The control of the coil currents is accomplished manually in the older installations and automatically in all new installations.

Manual Control

Degaussing installations that have the coil currents manually controlled are energized from

11651
11625

77.179

Figure 12-5.—Marking scheme for degaussing coil cables, feeder cables and connection and through boxes.

constant voltage d-c generators or from variable voltage motor-generators and are called (1) rheostat and (2) motor-generator installations, respectively.

Reversing switches are used to change the polarity of the coils, except where provision is made to accomplish this change in the design of the rheostat for the constant voltage supply

11621

Figure 12-6.—Marking of conductors in the single loop M coil connection box.

or in the generator control for the variable voltage supply.

In a Rheostat Installation the power for the degaussing coils is supplied by a constant-voltage d-c generator, and the coil currents are controlled by adjusting a rheostat connected in series with the coil and power supply. An installation in which rheostats are used to control the M, FI-QI, and FP-SP coil currents is illustrated in figure 12-7. Manually operated rheostats are used in some installations and motor-operated rheostats in other installations. In the manual type, the rheostat is adjusted locally at the degaussing switchboard by turning the rheostat handle. In the motor-operated type, the rheostat shaft is turned by a motor controlled from a remote station by means of a push-button. Motor-operated rheostats are equipped for manual operation in the event of an emergency.

In a motor-generator installation the power for the degaussing coils is supplied by a motor-generator, and the coil currents are controlled by adjusting a rheostat in the generator field circuit to vary the output of the generator. A single-line diagram of this type installation is illustrated in figure 12-8. The rheostats in the generator fields can be operated manually or by means of a motor to change the generator voltage and thereby adjust the coil current to the desired value.

An installation in which a combination rheostat and motor-generator is used to supply the coil currents is illustrated in figure 12-9. The M coil current is controlled by means of a variable-voltage motor-generator, and the FI-QI and FP-QP coil currents are controlled by means of rheostats.

The Degaussing Folder aboard each ship contains the forms which show the number of coils and type of circuit installed in the ship. Further details of the degaussing installation are shown on the degaussing plans carried aboard each ship.

11658

Figure 17-41.—GPI schematic (radar section).

1163

77.181

Figure 12-7.—M, FI-QI, and FP-QP coil degaussing installation with rheostat control.

The Degaussing Folder contains current setting charts that are prepared by the Degaussing Range when the ship is ranged and gives the degaussing coil currents to be used for any position on the earth's surface and any heading of the ship.

In most degaussing installations now in use the degaussing coil currents are set to the required values by an Electrician's Mate or other-authorized personnel. The current should be checked hourly and readjusted to the correct value when necessary. Degaussing coil currents

11064

77.182

Figure 12-8.—M, F, and Q coil installation with motor-generator control.

will change and require readjustment because of changes in degaussing-coil resistance caused by changes in cable temperature and changes in the voltage of the power supply for the degaussing coils.

POLARITY

The polarity of the degaussing coil currents is of particular importance. If the polarity of any of the degaussing coils is incorrect, the ship may very likely be in much greater danger from magnetic mines than if no degaussing were installed. The polarity of a coil should be checked by observing whether the pointer of the ammeter for the coil is on the POSITIVE (right) or NEGATIVE (left) side of the zero-center ammeter. Also, the polarity of a coil can be checked by observing whether the positive or negative plate glows in the neon indicator light for the coil. For positive polarity the right-hand electrode glows, and for negative polarity the left-hand electrode glows.

The direction of current in a degaussing coil is normally indicated by zero-center ammeters located on the degaussing control panel. The pointer will deflect to the right for positive (direction) current through the coil and to the left for negative current. The direction of

11655

77.183

Figure 12-9.—M, FI-QI, and FP-QP, and FP-QP coil degaussing installation with combination rheostat and motor-generator control.

current can be checked by a degaussing polarity indicator or a small compass. The polarity indicator dial is marked to denote the direction of current. When taking polarity readings with the indicator or small compass, move the device toward the degaussing coil until a good deflection is obtained, and no closer. The needle in the indicator or compass will reverse its

11656

magnetic polarity if the device is held too close to the coils. The indicator or compass should be checked after each test to be certain that the magnetic polarity of the needle has not reversed.

CHANGING COIL CURRENTS

The Degaussing Folder for each ship gives the current needed for each coil for all positions on the earth's surface and for all headings. One or more of the coil currents must be changed when one of the following conditions occurs:

1. When the ship passes from one Z zone to another.

The vertical intensity (Z component) of the earth's field, which is maximum at the magnetic poles and zero at the magnetic equator, is divided into a number of Z zones. The number of Z zones will vary, depending on the amount of compensation provided by the particular installation. Degaussing Chart No. 1 (fig. 12-10) illustrates the Z zones for the Atlantic and Indian Oceans. The reverse side of this chart contains the same number of Z zones for the Pacific Ocean. The coil settings are filled in for the various zones after the ship has been ranged.

2. When the ship passes from one H zone to another.

The horizontal intensity (H component) of the earth's magnetic field, which is maximum at the magnetic equator and zero at the magnetic poles, is divided into a number of H zones. Similar to the Z zones, the number of H zones will vary, depending on the degree of compensation provided by the degaussing system. A Degaussing Chart No. 2 (fig. 12-11) illustrates the H zones for the Atlantic and Indian Oceans and the reverse side contains the same number of H zones for the Pacific Ocean.

3. When the ship's heading changes from one sector to another.

The entire range of headings from 0 to 360° is divided into a number of sectors, each covering a part of the whole range of courses.

The Degaussing Course Corrections Setting Diagrams No. 1 for the FI-QI coil and No. 2 for the FI-QI and A coils are illustrated respectively in figures 12-12 and 12-13.

The Degaussing Course Correction Setting Tables No. 1 for the F and Q coils and No. 2 for the F, Q, and A coils are illustrated respectively in figures 12-14 and 12-15.

None of the degaussing coil currents are changed as long as the course remains in one sector (if the Z zone and H zone remain unchanged). The FP-QP coil current is NOT changed when the ship's heading or the ship's position changes. The following changes are necessary when changing from one sector to another or from one zone to another:

1. The M coil current must be changed when the ship moves from one Z zone to another. The M coil current is not changed when the ship moves from one H zone to another or when the heading changes from one sector to another.

2. The F, Q, FI-QI, L, and A coil currents are not changed when the ship moves from one Z zone to another, but must be changed if the ship moves to a different H zone, or if the heading changes to a different sector.

In a few ships, exceptional conditions may require a departure from the foregoing changes. In all cases, the Degaussing Folder will show the currents to be used.

Rheostat Installation

The degaussing coils in rheostat installations are energized by closing the main degaussing feeder switch and the individual coil switches in the proper polarity position with all rheostats set for maximum resistance. Set the current in each coil by cutting out resistance.

Adjust the rheostats for the M and FP-QP coils (if provided) until the M and FP-QP coil currents have the values specified in the Degaussing Folder for the ship's position. Adjust the rheostats for the F, Q, FI-QI, L, and A coils (if provided) until the coil currents have the values specified in the Degaussing Folder for the ship's position and heading. Check the coil currents periodically, and change the coil currents as required by changes in the ship's position and heading.

In installations employing motor-driven rheostats the polarity is changed only when the current is zero either by means of a motor-driven polarity changer and pushbutton, or by operating the rheostat through and beyond the position of maximum resistance. At this point, reversal of current will occur automatically because of the internal cross-wiring of the rheostat buttons on either side of this point, or by means of a motor-driven polarity changer actuated by the rheostat arm.

11-57

Figure 12-10.—Degaussing chart No. 1.

11658

69.15

Figure 12-11.—Degaussing chart No. 2.

11659

69.16

Figure 12-12.—Degaussing course correction setting diagram No. 1.

Motor-driven rheostats can be operated manually by turning the emergency handwheels in the event of failure of the motor-drive system. Rheostats having polarity changers operated by means of pushbuttons are provided with small handwheels for turning the polarity changer if the system should fail. Always reduce the current to zero before operating the polarity changer: otherwise, the contacts will burn out from operation under load.

In installations employing manually operated rheostats, the degaussing switchboard is usually located in the engineroom. This switchboard includes the disconnect switches for the F, Q, FI-QI, L, and A coils; reversing switches for the M and FP-QP coils; series resistors; fuses; and ammeters. A remote degaussing panel is located in the pilot house or chart house to permit changing the F, Q, FI-QI, L, and A coil currents as the ship changes heading.

11660

69.17G

Figure 12-13.—Degaussing course correction setting diagram No. 2.

This panel includes ammeters or polarity indicator lights for all coils and rheostats (rheostat pushbuttons); and reversing switches for the F, Q, and L coils or reversing switches for the FI-QI and A coils.

Telephone communications are provided between the remote and main panels. When the degaussing system is to be energized, the remote position (pilot house) may call the main degaussing switchboard station and have all currents set to the values called for in the degaussing folder. The remote position will then continue to maintain the currents in the FI-QI and A coils according to the ships location and heading changes.

MOTOR-GENERATOR INSTALLATION

The degaussing coils in motor-generator installations are energized by closing the disconnect switch to the motors with the generator field rheostats set for the maximum resistance, and operating the pushbutton to start the motor. The degaussing switchboard is usually located

in, or in the vicinity of, the engineroom near the degaussing motor-generators. This switchboard includes ammeters, pushbuttons for starting the motors, and the motor-driven field rheostat for the generator. In many installations in which the motor-generators are not located together, a separate switchboard is provided for each group of motor-generators.

After the motor has started, the currents in the coils are set by the pushbuttons that control the motor-driven field rheostats for the generators. The pushbuttons are located on the remote control panel in the pilot house or chart house, or on the degaussing switchboard. Zero-center ammeters mounted above the pushbuttons are used to determine whether the positive or negative pushbutton should be operated to obtain the specified currents. The positive pushbutton will operate the motor-driven generator field rheostat to increase the current in the positive direction (decrease the current in the negative direction). Conversely, the negative pushbutton will operate the motor-driven rheostat to increase the current in the negative direction (decrease the current in the positive direction).

SECURING

Degaussing coils should be secured according to instructions in the Degaussing Folder for the installation concerned. To cancel any residual magnetism due to the degaussing current, most installations require one or more of the coils to be secured by reversals. The procedure for securing a degaussing coil by reversals is as follows: (1) Starting with the maximum current specified in the Degaussing Folder, reduce the current to zero then increase to the starting value in the reverse direction. (2) Reduce the current to zero and then increase to 3/4 value in the original direction. (3) Reduce the current to zero and then increase to 1/2 value in the reverse direction. (4) Reduce the current to zero and then increase to 1/4 value in the original direction. (5) Reduce the current to zero and then increase to 1/8 value in the reverse direction. (6) Reduce the current to zero and secure.

AUTOMATIC DEGAUSSING

Automatic degaussing equipment is now installed in all new construction ships which require the coil current to be changed when the ship's heading changes.

Most automatic degaussing equipment aboard navy ships provides automatic compensation for the induced magnetization due to changes in ship's heading only. Mine warfare ships, however, require installations which also provide automatic compensation for the induced magnetization caused by the ship's roll and pitch. A brief discussion of degaussing installations for mine warfare ships is included later in this chapter.

A block diagram of a type SM or SSM automatic degaussing control equipment for HEADING COMPENSATION only is illustrated in figure 12-16. A heading signal is obtained from the ship's gyrocompass system. For an L coil or an FI-QI coil, the type SM control equipment derives a signal that is proportional to the cosine of the ship's heading. This signal is amplified and fed to the appropriate power supply so that its output is proportional to the cosine of the ship's heading. This is the variation needed to compensate for changes in the longitudinal induced magnetization caused by changes in the ship's heading. For the A coil, the type SM control equipment maintains the coil current proportional to the sine of the ship's heading.

A block diagram of a type GM automatic degaussing control equipment, installed on minesweepers for HEADING, PITCH, and ROLL COMPENSATION, is illustrated in figure 12-17. The additional signals needed to compensate for pitch and roll are obtained from the gyrocompass stabilizer system and fed to the automatic degaussing control equipment. A computer element in the control equipment utilizes the heading signal and the pitch and roll signals, and causes the degaussing coil currents to vary so that they compensate for changes in the ship's induced magnetism resulting from changes in heading, pitch, and roll of the ship.

All types of gyrocompass-controlled automatic degaussing control equipment require manual settings for magnetic latitude and magnetic variation. Also, all types of degaussing control equipment are equipped with manual controls for use if the automatic controls should become inoperative.

DEGAUSSING FOR MINE WARFARE SHIPS

The extremely low field requirements for mine warfare ships necessitates special ship design, proper control and stowage of magnetic materials, and degaussing protection that maintains accurately regulated currents at any angle of roll, pitch, and heading.

INPUT CATHODE FOLLOWER.—The input cathode-follower circuit is for the north and south d-c amplifiers, V902 and V903, respectively. The input cathode follower, V905, is a duotriode. The north and south reference voltages from the ground stabilization computer vary at the rate of 1 volt per mile in relation to the movement of the aircraft with respect to a point on the ground. These varying voltages are applied, through voltage dividers comprised of resistors R15 and R293 and R11 with R297, to the appropriate grids of V905. These changes in voltage slew (move) the origin of the sweeps, which represent the position of the aircraft, in the same direction in which the aircraft is flying and a distance indicative of its change in position measured in miles.

The other slewing voltages are applied through similar voltage dividers, composed of resistors R295, with R293 and R300 with R297, to the grids of V905. These voltages are supplied from the control box by manually adjusting the N/S slew control (R1 and R2) and are combined with the slewing voltage from the ground stabilization computer at the grids of V905. The automatic function of the slewing voltages from the ground stabilization computer is not affected; but by means of the local slewing voltages, the origin of the sweeps can be moved in any direction, so that the desired portion of the sweep can be brought into view and the target centered on the indicator. By means of relays and different voltage dividers in the input to V905, the indicator sweep range may be changed without affecting the ground stabilized presentation on the indicator. With the proper resistance values selected, after the target has been slewed to the center of the indicator, it will remain there even though the range is changed.

By means of slew switch S1, the manual slewing voltages can be cut in or out of the circuit; and with the ground GPI switch S2, the slewing voltages from the ground stabilization computer can be cut in or out. Therefore, by opening or closing these switches separately or together, either or both slewing voltages can be cut in or out of the circuit. If both are cut out of the circuit by opening both switches, the voltages on the grids of V905 are balanced. This gives a PPI presentation in which the start of the sweep is centered on the indicator screen.

The two silicon diodes, CR1 and CR2, are employed as limiters to prevent either grid of V905 from going more positive than 7.8 volts. This avoids the possibility of damaging this tube, the d-c amplifier, and other tubes in associated circuits. A voltage divider comprised of R921 and R920 maintains the negative sides of the silicon diodes (CR1 and CR2) at a positive potential of 7.8 volts.

The cathodes of V905 are connected to -150 volts through resistors R187 with R188 and R189 with R190. The outputs from the cathode followers are taken from R187 and R189.

D-C AMPLIFIER.—With each input cathode follower are associated two d-c amplifiers. A pentode type tube is used in each d-c amplifier stage. The amplifier fed by the north section of the input cathode follower, V905, amplifies the north d-c input slewing voltage and provides a north-slewing voltage for the indicator. The north d-c amplifiers and its complement, the south d-c amplifier, effectively from a push-pull circuit which affects the north-south sweep in the indicator. Since all of these amplifiers are identical, only one will be discussed.

The north output of the input cathode follower is applied through variable resistor R187 and fixed resistor R184 to the grid of the d-c amplifier tube, V902. The variable resistor N ZERO SET is adjusted, with all input slewing voltages at zero (slew switch off and GPI switch off), until the north d-c amplifier is operating at the proper quiescent level for centered presentation. Resistors R170, R172, R174, and R176 form a voltage-divider network between a +150 volts d-c and a -150 volts d-c. The N/S gain control, R178A, adjusts the d-c feedback from the output cathode follower through the series resistors R172, R174, R178A, and R179 to the grid of the d-c amplifier, V902, thereby controlling the gain of the amplifier. This gain control is ganged to a similar control, R178B, for the south d-c amplifier, V903, so that the gain of these complementary stages is always the same. Variable resistor R172, N OUTPUT, adjusts the output voltage to obtain the proper bias on the sweep driver stages in the indicator. This bias voltage can be measured at test jack C1 and in a static state (no slew applied) is -19 volts d-c.

OUTPUT CATHODE FOLLOWER.—Since the output of the d-c amplifier is applied to a low-impedance input in the sweep amplifier, the d-c amplifier is coupled through a cathode-follower stage. A duotriode tube is used, and each section functions as a cathode follower for one d-c amplifier. The output of the north d-c

11666

77.185

Figure 12-17.—Block diagram of type GM automatic degaussing control equipment for heading pitch, and roll compensation.

Four basic types of degaussing coils are installed in mine warfare ships (fig. 12-18). The M, or main coil, is located in a horizontal plane and compensates for the induced vertical magnetism of the ship. The A, or athwartship coil, is located in a vertical fore and aft plane and compensates for the induced athwartship magnetism of the ship. The L, or longitudinal coil, is located in a vertical athwartship plane and compensates for the induced longitudinal magnetism of the ship.

Each M, A, and L coil has an associated and identically located P, or perm coil (not shown) which compensates for the permanent portion of the ship's magnetism.

Mine warfare ships were initially provided with gyro controlled automatic degaussing control systems. A magnetometer controlled system has now been developed which is replacing the gyro controlled systems.

GEM-2 System

The GEM-2 automatic degaussing control system is a magnetometer controlled system that is replacing the gyro controlled GM-2

11667

111.49

Figure 12-18.—M, A, and L degaussing coils.

system used on coastal minesweeper ships (MSC) and coastal minehunter ships (MHC).

The change from GM-2 to GEM-2 is a conversion rather than a complete system replacement. The GM-2 system (fig. 12-17) did not always provide continuous satisfactory degaussing protection. Operator errors in making proper H-zone, Z-zone, and magnetic variation settings often gave unsatisfactory compensation. Mechanical faults in the computer, stabilizer or gyro could also contribute to unsatisfactory protection. The GEM-2 system (fig. 12-19) removes these objectionable features. The possibility of operator error is reduced considerably; after the ship is calibrated at a degaussing range, the controls are locked in place and the operator only turns the equipment on and off.

The new system also removes the mechanical features that were subject to failure. The advantages of the new system are clear when figures 12-17 and 12-19 are compared.

MAGNETOMETER PROBE.—The magnetometer probe assembly (fig. 12-20) contains three mutually perpendicular elements which

11668

77.185

Figure 12-19.—Block diagram of GEM-2 automatic degaussing control system.

furnish signals proportional to the earth's field to the M, A, and L channel signal amplifiers.

MAGNETOMETER SIGNAL AMPLIFIER.—The signal amplifiers convert the low power level signal received from the sensing elements of the magnetometer to signals appropriate for driving the two stages of magnetic amplifiers for each automatic channel. These amplifiers are of the transistor type and are contained on printed circuit boards. All subassemblies are plug-in type printed circuit boards. Go-no-Go testing facilities are incorporated in the equipment so that the cause of a failure can be found in a manner similar to the operation of a simple tube tester.

11669
11670

111.52
Figure 12-20.—Three-axis magnetometer probe assembly.

The equipment can be restored to satisfactory operation by replacing a faulty plug-in printed circuit board with a new one from the ship's onboard repair parts.

CONTROL PANEL.—The control panel for the GEM-2 system (fig. 12-21) shows the arrangement and controls for manual or automatic operation of the system. Under manual control the magnitude and polarity of the degaussing current is controlled by adjustments on this panel.

EMS Systems

Automatic electronic degaussing systems designated EMS have been developed and installed on various mine warfare ships of the MSI, MSC, and MSO classes.

All the EMS systems are magnetometer controlled. These systems utilize transistors with printed circuits and static type power supplies. The following coverage is on the EMS-4 system which is being installed on all MSO-421 class minesweepers.

DESCRIPTION OF UNITS.—The Degaussing System is comprised of three units: the degaussing control panel, the magnetometer probe assembly, and the degaussing control test equipment.

Degaussing Control Panel.—The degaussing control panel (fig. 12-22) which contains four slide-mounted drawers, is mounted on a bulkhead in the ship. This unit contains all the operating controls for the degaussing system. Electrical cables connect the degaussing control panel to the magnetometer probe assembly and to the ship's degaussing coils.

Magnetometer Probe Assembly.—The magnetometer probe assembly (fig. 12-22) mounted on the ship's mast, senses the magnetic field strength along three mutually perpendicular axes, and feeds this information to the degaussing control panel by means of an electrical cable.

Degaussing Control Test Equipment.—The degaussing control test equipment (fig. 12-22) includes a milligauss meter, a d-c ammeter, and pull-out tools for removing subassemblies. The meters are used to check the operation of the degaussing system.

Other types of automatic degaussing control equipment are the FM and RM types. The FM is a magnetic amplifier type of control that controls the exciter field of the degaussing motor-generator. The RM is also a magnetic amplifier type of control that controls the motor of the motor-operated rheostat. The rheostat is in series with the degaussing coil that is connected across the ship's constant-voltage d-c power supply. Refer to the manufacturers' instruction books furnished with the specific equipment for more detailed information concerning automatic degaussing control equipment. Also, the Electrician's Mates 1 and C training course contains additional information on automatic degaussing control equipment.

COMPASS COMPENSATION

Degaussing coils (either manual or automatic types) must produce large magnetic fields in order to provide satisfactory degaussing. Unless neutralized in the vicinity of the magnetic compass, these fields may be of sufficient magnitude to make the compass useless for navigation. The purpose of compass compensating coils is to set up a "compensating" magnetic

11670

111.51

Figure 12-21.—Front panel of control unit for GEM-2 automatic degaussing control system.

Figure 12-22.—Automatic electronic degaussing system, type EMS-4. 27.284

11672

field which is equal and opposite to the degaussing coil field in the immediate vicinity of the compass.

Almost all degaussing coils create a vertical component of magnetic field at the compass. A vertical component at the compass causes the compass to deviate when the ship heels even though it will usually cause no deviation when the ship is on an even keel. To compensate for the vertical component of magnetic field caused by the degaussing coils, a compass compensating coil, called the heeling coil, is used. The heeling coil is placed in a horizontal plane around the binnacle usually at the level of the magnetic compass needle, with its vertical axis passing through the center of the compass. A heeling coil is used in all types of compass compensating coil assemblies.

In addition to the vertical component of magnetic field, degaussing coils also create a horizontal component of magnetic field at the compass. The horizontal component of magnetic field at the compass causes compass deviations whether or not the ship is on an even keel. The "deviation due to degaussing" on any heading can be obtained by subtracting the magnetic compass reading with degaussing "off" from the magnetic compass reading with degaussing "on". The horizontal component of magnetic field is compensated by two mutually perpendicular vertical coils or pairs of coils.

The magnitude of the magnetic field produced at the compass by a degaussing coil varies with the degaussing coil current. To compensate this field, the magnetic field produced by the compass compensating coils must also vary in the same way. This is arranged by connecting the equipment so that the compass compensating coil current is always the same fraction of the degaussing coil current. When this fraction is so adjusted that the magnetic fields produced by the degaussing coil and the compass compensating coil are equal and opposite, the balance between them is maintained no matter how the degaussing coil current varies. Doubling the degaussing coil current, for example, would double the magnetic field produced at the compass by the degaussing coil, and would also double the field produced by the compass compensating coils used to compensate the degaussing coil.

The supply used for the compass compensating coils is usually the voltage drop across a fixed resistor connected in series with the degaussing coil or the voltage drop across a number of turns of the degaussing coil. This voltage is proportional to the degaussing coil current, hence, the current which the supply sends through the compass compensating coils is also proportional to the degaussing coil current. This is the condition which must be satisfied to insure that compass compensation will not be disturbed by a change in degaussing coil current.

Compass compensating coils are usually installed by the personnel at a naval shipyard or degaussing activity, not by ship's forces. If it is ever necessary for ship's forces to install compass compensating coils, the installation should be made in accordance with the instruction manual furnished with the coils.

Compasses are usually compensated for degaussing by personnel at a naval shipyard or a degaussing activity. At times, however, ship's forces may have to compensate compasses after repairs to the compass compensating coil installation. For this reason, instructions on compass compensation listed in BuShips Technical Manual chapter 9810 Section III, should be followed.

Basically, compass compensation for degaussing consists of adjusting the resistors in the control boxes so that the compass points in the same direction irrespective of whether the degaussing coils are turned on or off.

The general term "compensation" includes the three following distinct steps or procedures:

(a) A preliminary or "dockside" compensation.

(b) A "final" compensation.

(c) A swing for deviations.

Each of these three steps is described in BuShips Technical Manual chapter 9810.

MAINTENANCE

The degaussing installation should be carefully maintained particularly to prevent deterioration resulting from moisture gradually entering the cables. Since the degaussing system consists of electrical cables, rheostats, ammeters, connection boxes, motor-generator sets, and costly automatic control equipment it must be maintained in conformity with the instruction for the maintenance of electrical equipment given in applicable chapters of the NavShips Technical Manual (Chapters 9600 and 9810) and applicable technical manuals for the equipment installed.

11073

amplifier, V902, is applied through resistors R181 and R166 to the grid of one section of the cathode-follower tube V901, and the output of the complementary south d-c amplifier is applied to the other section of V901. The resistor network, composed of resistors R183, R181, and R168, forms a voltage divider to obtain the proper plate voltage for the d-c amplifier and, together with resistor R166, determines a fixed bias for the output cathode follower. Capacitor C129 provides a low-impedance path for any a-c ripple which may be present from the cathode of the output cathode follower back to the grid of the d-c amplifier. This feedback greatly attenuates any a-c ripple and prevents "jitter" of the presentation on the indicator.

The output is taken from the cathode of V901 (north), and is used to establish the bias on the north sweep driver. Similar outputs from the other output d-c amplifiers establishes the bias on the south, east, and west sweep drivers for the indicator. By varying these bias voltages, the start of the sweep on the indicator can be changed as desired, or as dictated by the position of the aircraft.

OUTPUT LIMITER.—In order to limit, at the proper peak and minimum values, the slewing bias from the output cathode follower, two parallel diode limiters are used. Four silicon diodes are employed with two in the north d-c amplifier circuit and two in the south d-c amplifier circuit. A potential of approximately -9 volts is applied to the negative sides of CR5 and CR6 by a voltage divider. A potential of approximately -29 volts is applied to the positive sides of CR3 and CR4 by another voltage divider. The double limiting provided by these circuits limits the available slew range to approximately 2 radii at the output and, in addition, protects the sweep drivers in the indicator from being overdriven by limiting their bias to a range from -9 volts d.c. to a -29 volts d.c. The output limiters, along with a maximum local slewing voltage of ±50 volts and a maximum ground stabilization slewing voltage of ±150 volts, determine the overall slewing ranges of the indicator.

SWEEP DRIVER AND CLAMPER.—There are four identical sweep-driver circuits in the indicator. Each sweep-driver circuit affects one phase of the sweep; that is, either north, south, east, or west. The sweep voltages from the sweep synchro in the antenna are passed directly into the indicator. These voltages are applied to the sweep-driver stages for amplification prior to being coupled to the appropriate deflection coil of the indicator. Since all the circuits are identical, only one circuit will be discussed.

A phase of the sweep input is fed through C101 to the "A" cathode and the "B" plate of V101, a duotriode operated as a two-way clamper, and through C104 to the grid of the sweep driver, V103. The negative-going clamp-gate square wave is applied to the grids of the duo-clamper. The duration of the negative half cycle of this square wave is equal in time to the duration of the sweep sawtooth waveform. The slew voltage is applied to the "A" plate and the "B" cathode of V101. Since the clamp-gate and sweep waveforms are equal in duration, application of the clamp-gate waveform to the clamp tube, V101, cuts it off and allows the sweep voltage waveform to be felt on the grid of the sweep driver, V103, and varies its conduction. During the blanking time of the sweep, the clamp action (known as synchronized clamping) is such that the grid of the sweep driver is clamped to a desired slew potential, to insure the proper starting point of the sweep. This desired slew potential determines the quiescent plate current in the driver tube, and thus controls the starting point of the sweep seen on the indicator. In this manner, the origin of the sweep can be moved or slewed on the indicator to view any portion of the sweep. If the bias on the sweep driver is made less negative, more current will flow through its associated section of the yoke. Therefore, the origin will move in the direction and distance represented by the amplitude of the output of the sweep driver; R101 is the N/S centering adjustment for the indicator.

1165

Preventive Maintenance

When the system is not in normal use, all coils should be energized at least once a week to the maximum current specified in the Degaussing Folder and operated for at least four hours with the current in one direction. Then reduce the current to zero and energize the coils momentarily with maximum current in the opposite direction.

Check each degaussing coil for grounds by insulation resistance measurements using a 500-volt megger. When the source of supply for degaussing coils is from rectifiers, the rectifiers must be disconnected prior to using a 500-volt megger on the degaussing coils to prevent damage to the rectifiers. These measurements should always be made with the same degaussing equipment connected in the circuit and as closely as possible under similar conditions of temperature and humidity. The date and reading of the insulation resistance to ground should be recorded each week on the Ship's Force Degaussing Maintenance Record in the Degaussing Folder. These measurements should be taken between the coil disconnect switch and ground. In the F, Q, and A or I, P, and A coils that have a reversing switch on the coil side of the disconnect switch, the measurement should be made with the reversing switch in the CLOSED position. Also, this measurement should be made just before the weekly energizing of the coils so that the comparative readings are obtained under similar conditions. By comparing these weekly readings it is possible to detect abnormal decreases in resistance and take the necessary corrective action before failure occurs. When abnormal decreases are indicated the various components of the circuit should be isolated and the insulation resistances checked individually to determine the cause of the low reading.

The connection boxes may accumulate considerable amounts of water due to condensation and leakage through improperly seated gaskets. The moist atmosphere in the box will gradually force moisture into the cable ends and reduce the insulation resistance. If this condition is not checked in time, the cable may be ruined and require replacement. Therefore, remove the connection and through-box drain plugs once a month to allow any accumulated water to run out. The date that each box is drained should be recorded on the Ship's Force Degaussing Maintenance Record (NavShips Form 1009) in the Degaussing Folder. Boxes that have abnormal accumulations of water should be opened, dried out, and the gaskets checked and replaced if necessary.

Remove corrosion on rheostat contact buttons with fine sandpaper and coat the buttons lightly with a graphite lubricant. Remove accumulations of dirt and dust from automatic degaussing control equipment to facilitate the natural flow of air around the components, and thus eliminate the possibility of overheating. Use a vacuum cleaner or bellows; do not use compressed air.

The maintenance requirements for manual degaussing systems are not as extensive as the automatic degaussing systems. Figure 12-23 shows a semi-annual maintenance requirement for cleaning and inspecting a manual degaussing switchboard. Automatic degaussing switchboards and remote panels require more frequent cleaning and inspection as shown by the quarterly maintenance requirement card (fig. 12-24) for the automatic degaussing switchboard and remote panel.

Observe the preventive maintenance requirements for automatic control equipment and motor-driven rheostats, as outlined in the applicable technical manual. Also, observe the maintenance of electrical equipment and electrical safety precautions, as required by Chapter 9600 of the NavShips Technical Manual.

Conduct weekly linearity checks, as required on ships equipped with automatic degaussing units in accordance with the applicable technical manual. Make weekly entries on the Ship's Force Degaussing Maintenance Record (NavShips 1009) in the Degaussing Folder.

Corrective Maintenance

Corrective maintenance consists principally of locating and eliminating grounds in the various coils, circuits, and components of a degaussing system.

Grounds in a degaussing conductor can be located by breaking the conductor into its component sections by opening connections at connection and through boxes, and testing each section of the conductor individually. Grounds in FEEDERS and control equipment CIRCUITS can be located by isolating the different components.

When making these tests, reconnect all ungrounded connectors to their terminals immediately after they have tested clear, to prevent misconnection later. To locate grounds in degaussing circuits, proceed as follows (observe

14. Oil, Symbol 2110 TH

PROCEDURE

Preliminary

a. De-energize the degaussing switchboard power supplies and tag "Out Of Service."

1. Clean and Inspect the Switchboard.
   a. Open or remove access covers as applicable.
   b. Test with voltage tester to ensure all power supplies are de-energized.
   c. Vacuum the switchboard and components. Use dusting brush to remove dirt from hard to reach areas.
   d. Wipe the switchboard and components with a rag to remove grease deposits.
   e. Grease the rheostat shaft bearings and oil the bearing points on switches. Wipe off excess lubricants.
   f. Inspect rheostat faces for evidence of overheating and pits. Clean with sandpaper as necessary.
   g. Inspect mechanical components to ensure freedom of all moving parts. (Cont'd on Page 2)

9. Inhibited methyl chloroform
10. Safety tags

PROCEDURE

Preliminary

a. Obtain permission from Engineer Officer to secure the switchboard for inspection and cleaning.
b. Secure power at ship service switchboards and tag "Out Of Service."

1. Clean and Inspect Switchboard and Switchboard Equipment.

a. Open front panels and remove rear panels.
b. Test power transfer switch and interconnection block with the multimeter to ensure power is de-energized.
c. Connect insulated grounding cable to good ground and ground out all connections in switchboard.
d. Vacuum all components within the switchboard to remove dust and dirt.

WARNING: Avoid prolonged contact with inhibited methyl chloroform. Provide adequate ventilation.

e. Wipe any grease or oil deposits using a rag dampened with inhibited methyl chloroform.

precautions required when using a 500-volt megger on rectifier circuits):

1. Open the supply switch for the degaussing coil and close the reversing switch in either position.

2. Disconnect the feeder conductors from the degaussing coil at the feeder connection box.

3. Measure the insulation resistance to ground for each of the feeder conductors. If the insulation resistances are satisfactory in accordance with the manufacturer's technical manual and Chapter 9600 of NavShips Technical Manual, the feeder conductors and the equipment connected to them are clear of objectionable grounds. If the insulation resistance to ground is unsatisfactory for either one or more of the feeder conductors, proceed in accordance with the method for locating grounds in feeder conductors, as described in the instruction book accompanying the installation.

4. Measure the insulation resistance from the degaussing coil to ground. If the insulation resistance of the degaussing coil is satisfactory in accordance with Chapter 9600, NavShips Technical Manual, no further insulation tests on the coil are necessary.

DEGAUSSING DEFINITIONS

DEGAUSSING COIL.—One or more loops of degaussing cable; each loop encircles a different total area and is connected in series with other loops to form the required coil.

PARALLEL CIRCUIT.—An arrangement of conductors connected such as to provide two or more complete and independent electrical paths through a coil or loop and having a common source of supply.

COIL SECTION.—A section of a degaussing coil cable is the length of cable between two successive connections or through boxes.

PERMANENT MAGNETISM.—That portion of the magnetic field of a ship due to the earth's magnetic field and the orientation of the ship with respect to this field at the place where the ship was built, the material of which the ship was constructed, and other factors.

INDUCED MAGNETISM.—That portion of the magnetic field of a ship which is proportional to the strength of the earth's field through the ship.

EFFECTIVE TURNS.—The number of turns which are effective in producing a magnetic field under the ship. The difference between the number of series conductors in a coil or loop in which the current flows in a counterclockwise direction and the number of series conductors in which the current is flowing clockwise (called reverse turns) when viewed in accordance with polarity convention for each coil.

AMPERE TURNS.—The product of the current flowing through the coil or loop and the number of effective turns.

LOOP.—One or more turns of the conductors of a degaussing cable encircling a specific area. Different loops connected in series form a degaussing coil, for example: FI, FI2, QI, and QI2 loops are connected in series to form a FI-QI coil. In conserving cable, the conductors used for different loops encircling the same area may be contained in the same cable, for example, an FP and FI loop may both be contained in an F cable.

TURN.—One complete lap around the perimeter of a specified area by a coil or loop. One turn consists of one conductor or 2 or more conductors connected in parallel.

SERIES RESISTORS.—A resistor connected in series with the degaussing coil and used to limit the coil to its maximum design current. Where series resistors are used, the power for the compass compensating coil is usually provided by utilizing, in part, the voltage drop across this resistor and thereby varying the effect of the CC coils proportionally with the degaussing coil currents.

"THREE-COURSE EMERGENCY."—A manual three-step course correction, accomplished by a switch or switching system which provides for changes in the polarity and magnitude of the current in the FI-QI, L and A coils to compensate for changes in induced magnetism due to changes in the heading of the ship. For this purpose, three values of ampere turns are used. With an FI-QI coil, for example, zero ampere turns are used for headings in the general direction of magnetic East, a positive value for heading in the general direction of Magnetic North and a negative value of equal magnitude for heading in the general direction of magnetic South.

11377

REMOTE CONTROL PANEL.—This unit contains the necessary meters, electrical circuits, and controls to enable an operator to monitor all degaussing coil currents and to control manually by Three-Course Emergency the degaussing coil currents normally controlled automatically by the AUTODEG control unit.

AUTOMATIC DEGAUSSING — CONTROL UNIT.—This unit, by utilizing a signal from the ship's gyro compass system (heading only) or (heading, roll, and pitch) varies the ampere turns with changes in heading, or heading, roll, and pitch automatically. This equipment incorporates a "Three-Course Emergency" control and generally an additional manual control.

COMPASS COMPENSATING CONTROL BOX.—A watertight enclosure having a removable cover and containing three sets of control resistors. Each set of control resistors consists of fixed resistors, a variable resistor, and jumpers. By means of adjusting the control resistors, the compass compensating coil currents are regulated to give the desired compass compensation.

DEGAUSSING FOLDER.—The degaussing folder (NavWeps 8950/40) is an official ship log which contains instructions for operation of the degaussing system, degaussing charts and values for coil settings, Installation Certificates, and a log section showing all pertinent details of action taken on the ship's degaussing system for the information of degaussing authorities. The Degaussing Folder is issued to a ship by the Degaussing Facility which renders the initial magnetic treatment. Minesweepers use degaussing folder (NavWeps 8950/50) which is classified confidential when filled in.

INSTALLATION CERTIFICATES.—Installations Certificates are official NavWeps forms. Each form is divided into five parts; layout, schematic electrical diagram, circuit data, remarks, and certification. BuWeps Instruction 8950.2B of 19 April 1966, Degaussing Instructions, Forms, Records And Reporting Procedures, contains additional information and sample NavWeps forms.

ANCHOR WINDLASSES

Anchor windlasses are installed on ships primarily for handling and securing anchor and chain used for anchoring the ship. In addition, most windlasses are provided with capstans or gypsy heads for handling line and for mooring and warping operations.

Windlasses are located in the bow of the ship for handling the bow anchors.

Landing ships capable of beaching and retracting from the beach are provided with a separate anchor winch to handle the stern anchor used during these operations.

Anchor windlasses are designed to meet specified conditions as follows:

a. Hoist the anchor and chain from 60 fathoms depth at specified speed.
b. Hoist anchor and chain from 100 fathoms at no specified speed.
c. Stop and hold the anchor and chain by means of the wildcat brake.
d. Develop a specified rope speed on the capstan or gypsy head.
e. Withstand a static load on the capstan or gypsy head equal to the minimum breaking strength of the specified size of rope.

TYPES AND CLASSES

Two general types of windlasses are installed on naval ships. These are the horizontal shaft type and the vertical shaft type. These types are subdivided into classes depending on the power source. These classes include the following:

a. Electric hydraulic drive
b. Electric drive
c. Steam drive
d. Hand drive

The essential parts of a windlass, regardless of type and class, are the prime mover, gear transmission, chain wildcat and brake, head for handling line and control means.

Horizontal shaft windlasses are usually made as a self-contained unit with the windlass and prime mover mounted on the same bedplate.

Vertical shaft windlasses have the power source located below deck with only the wildcats and heads showing above the deck.

Electric-Hydraulic Windlasses

Electric-hydraulic windlasses are installed on ships having alternating current power supply. They are particularly adapted for anchor handling with its varying load conditions due to the wide range of speed and torque characteristics afforded. The hydraulic drive was developed to overcome all the operating and

11678

installation objections inherent with either steam or direct electric driven windlasses. The electric hydraulic windlass drive is similar to the electric drive except, instead of having the electric motor coupled direct to the reduction gearing, the power is transmitted from the electric motor through a variable stroke hydraulic transmission to obtain a wide range of output shaft speed.

The electric motor for a hydraulic windlass is usually a single-speed, squirrel-cage type. Electric control is required only for light starting duty as the motor is started under no load condition. The motor is direct coupled to the pump unit of the hydraulic transmission also known as the A-end. Fluid under pressure is delivered from the A-end to the hydraulic motor unit, B-end, through piping. The B-end is coupled to a suitable reduction gear which drives the windlass shaft.

Windlass speed is determined by varying the stroke of the pump A-end. This is done by control handwheels, located on the weather deck and at the pump. These handwheels also control the direction of rotation of the windlass and are suitably marked. The stroke at which the A-end is set determines the quantity of hydraulic fluid delivered to the B-end, which in turn determines the speed at which the B-end rotates as its displacement is constant.

The power plant of a typical hydraulic windlass installation for large combatant or auxiliary vessels consists of two units. Each unit comprises a constant-speed, horizontal, squirrel-cage, electric motor driving a variable stroke hydraulic pump through suitable reduction gearing. The electric motors are provided with magnetic brakes designed to hold 150 percent of the motor-rated torque and to set on loss of power to prevent the anchor dropping in case of power failure. The power units are arranged, port and starboard, in the windlass room. Normally the port unit drives the port windlass half, and the starboard unit, the starboard half. Transfer valves, however, are provided in the oil lines which, when properly set, allow the port power unit to operate the starboard windlass, and vice versa.

Electric Windlasses

Electric windlasses are powered by an electric motor which drives a wildcat(s) and head(s) direct through suitable reduction gearing. The electric power for the motor is either alternating current or direct current.

Destroyers are provided with a direct motor-driven windlass with a single wildcat mounted vertically and a working head located above the wildcat and keyed to the vertical shaft. This system is discussed in more detail later.

Cargo ships, transports, and auxiliary ships are generally provided with horizontal shaft, self-contained, electric drive windlasses with the motor and reduction gearing located on the windlass bed plate on the open deck. These windlasses have combined facilities for anchor handling and warping and consist of two declutchable wildcats on the main shaft and two warping heads on the shaft ends, all driven through suitable reduction gearing by the electric motor.

The motors are reversible, variable speed, 230-volt d-c and are provided with magnetic brakes to hold the load in case of power failure or under service conditions. Controls are of dual magnetic type to provide both straight reversing characteristics for warping and dynamic lowering characteristics for anchor handling. Transfer switches allow selection of the proper characteristics. When used for anchor handling, the control usually provides five speeds in each direction with adequate torque in hoist directions and dynamic braking in all lowering points. For warping, the control characteristics are substantially identical in both directions. A single controller master switch is provided and located on deck adjacent to the windlass.

DESTROYER ANCHOR WINDLASS

The anchor windlass installed aboard certain destroyers consists of a two-speed motor directly connected through reduction gears to a vertical shaft on which are mounted a capstan and a wildcat (fig. 12-25.) The capstan and wildcat are located on the weather deck, and the electric motor and the across-the-line starter are located in the windlass room on the next deck below. The windlass is designed to operate in both directions to raise or lower either the starboard or port anchor.

Construction

The windlass is driven by a two-speed (full speed and one quarter speed), 3-phase, 440-volt, 60-cycle motor connected to the reduction gear by a controlled torque coupling. The controlled torque coupling is provided to prevent

11680

11679

3.224

Figure 12-25.—Anchor windlass.

undue stresses when the anchor is being housed. In all cases the anchor should be housed by shifting the drum master switch to the low speed position before the anchor enters the hawsepipe.

An electric brake, mounted just below the controlled-torque coupling, will release when power is applied and will set when power is disconnected or fails. The electric brake is designed to stop and hold 150 percent of the rated load when the anchor and chain are being lowered at maximum lowering speed, in the event of power failure.

The wildcat is designed to hoist one anchor and 60 fathoms of 1 1/4-inch dielock chain in not more than 10 minutes on the high speed connection without exceeding the full-load rating of the motor. On the low-speed connection the wildcat is designed to hoist the anchor and 60 fathoms of chain without overloading the motor, and to exert a pull on the chain at least three times that required to hoist the anchor and 60 fathoms of chain.

The capstan is designed to heave a 6-inch circumference manila line at a speed of 50 feet

11680

per minute with a line pull corresponding to the full-load motor torque.

The capstan head is keyed directly to the drive shaft while the wildcat is connected to the drive shaft through a driving head and a locking head. The wildcat is keyed to the driving head and the locking head is keyed to the drive shaft. Vertical blocks sliding in slots in the locking head are raised (by the locking handwheel) into slots in the driving head to connect the two heads. The mechanism is called the locking gear. The wildcat and sleeve run free on the same shaft until connected to the shaft by a locking head located below the weather deck. The capstan can be run independently for warping by disconnecting the locking head and holding the wildcat by means of the brake band on the brake drum. The handwheel can be pinned in the LOCKED or UNLOCKED positions and should always be fully locked or fully unlocked.

A handbrake is provided on the wildcat shaft to control the anchor handling. It is designed to operate in either direction of rotation of the wildcat and to stop and hold the anchor when dropped from a depth of 45 to 60 fathoms. The brake is operated by means of a handwheel located on the weather deck and a duplicate handwheel in the windlass room.

Operation

The windlass is operated by a drum master switch on the weather deck and a duplicate switch in the windlass room. It is important to remember that if the windlass is run with the locking handwheel in the LOCKED position, the wildcat will revolve. In this case, if the chain is engaged in the whelps on the wildcat, the chain should be free to run. Exercise care to select the proper direction of rotation and be certain that the windlass is properly lubricated.

The motor can be operated from either master switch No. 1 (on the weather deck) or from master switch No. 2 (in the windlass room) but master switch No. 1 predominates. When the associated on-off selector switch located on master switch No. 1 is operated to the ON position, master switch No. 1 takes over control from master switch No. 2 (if both switches are operated simultaneously).

The anchor windlass is used alternately to handle either the starboard or the port anchors. The windlass is operated by a reversible motor in either of two directions. These directions may be hoist for the starboard anchor (lower for the port anchor) and hoist for the port anchor (lower for the starboard anchor). However, only one anchor can be handled at a time. The nomenclature on the controllers refers to the hoist directions for both anchors.

The motor starter (fig. 12-26) is equipped with four thermal overload relays to protect the motor against overloads. Overload relays 1SOL and 2SOL are in the slow-speed motor circuit and overload relays 1FOL and 2FOL are in the fast-speed motor circuit. If an overload occurs in the slow-speed or fast-speed circuit, the SOL or the FOL relays will operate to trip the slow-speed, S, or the fast-speed, F, contactors respectively. The motor can be operated in the event of an emergency by holding either of the EMERG-RUN pushbuttons down and operating the master switch in the usual manner. To reset the overload relays, press the OVERLOAD RESET pushbuttons in the event of an overload or voltage failure. The master switch must be returned to the OFF position to restart the motor.

To start the motor in the port (hoist) direction for slow speed by master switch No. 1, operate the associated on-off switch to the ON position and move the controller handle forward to the SLOW PORT (hoist) position. This action closes contacts MS11 momentarily to energize the operating coil of relay CR1 and to close its contacts CR1a to provide a holding circuit for relay CR1, and to open its normally closed contacts CR1d to prevent operation of relay CR2 at this time. At the same time, contacts CR1b close to prepare the circuit to controller contacts MS12 and MS13, and contacts CR1c close to prepare the circuit to controller contacts MS14 and MS15.

When the controller handle is moved further toward the SLOW PORT position, contacts MS11 open; controller contacts MS12 close to energize the operating coil, P, and close the port contactor in the motor starter; also, contacts, Pa, close to provide the circuit to the motor brake relay, BR. At the same time, controller contacts MS14 close to energize the operating coil, S, and close the slow-speed contactor in the motor starter. Contacts Sa close to energize the brake relay, BR, and close its contacts to release the motor brake. Also, the normally closed contacts, Sb (in the circuit to the operating coil, F, of the fast-speed contactor), open. The motor is now connected for hoisting the port anchor at slow speed.

11681

77.186

Figure 12-26.—Reversing across-the-line starter for two-speed anchor windlass.

11682

When the controller handle is moved further to the FAST PORT position, contacts MS15 close and contacts MS14 open. Contacts MS15 close before contacts MS14 open so that the operating coil, S, is kept energized through the normally closed contacts, Fb. When contacts MS14 open, operating coil, S, deenergizes and closes contacts Sb to energize the operating coil, F. This action opens contacts Fb to deenergize the operating coil, S, and open the slow-speed contactor. When the slow-speed contactor opens, contacts Sb close to complete the circuit to the fast-speed contactor in the motor starter. The motor is now connected for hoisting the port anchor at fast speed.

To hoist the starboard anchor, the same sequence occurs, except that controller contacts MS13 energize the operating coil, ST, to close the starboard contactor instead of controller contacts MS12 energizing the operating coil, P, to close the port contactor.

If it is desired to operate the motor by master switch No. 2, operate the associated on-off switch to the ON position and move the controller handle to the PORT or STARBOARD SLOW position. This action closes contacts MS21 momentarily to energize the operating coil of relay CR2 (if relay CR1 is not energized). The sequence of operation for master switch No. 2 is the same as that for master switch No. 1, except that contactors P, ST, S, and F are energized through the CR2 contacts instead of through the CR1 contacts. Master switch No. 1 can be locked out by turning the selector switch to the No. 1 LOCKED position. In this position the selector switch opens the circuit to relay CR1 and prevents its operation.

Maintenance of the electrical components of the anchor windlass should be in accordance with the instructions listed in chapters 6 and 9 of this training course. More detailed information concerning the maintenance of this equipment is contained in the manufacturers' instruction books furnished with the specific equipment.

ELEVATORS

The elevator installations aboard aircraft carriers usually consists of hydraulic or electric types for airplane elevators and electro-hydraulic or electromechanical types for freight, mine, bomb, torpedo, and ammunition elevators. Only the electric elevator and the electro-hydraulic elevator will be discussed in this chapter.

ELECTRIC ELEVATORS

The platform on electric elevators is raised and lowered by groups of cables which pass over sheaves and then to the hoisting machinery drums. The hoisting drums, coupled together, are driven through a reduction gear unit by an electric motor.

The motor is of the two-speed type. The control arrangements being such that the elevator starts and runs on the high speed connection, the low speed being used for deceleration as the elevator approaches the upper or lower limit of travel.

The 2-speed electric motor is controlled through a system of contactors, relays, limit switches, and selector switches. Automatic operation is obtained by selecting the levels between which the platform is to run. The start pushbutton can then be used to close contactors through safety switches to accelerate the platform from low speed to high speed. Just before reaching the desired level, the control transfers the motor to the low-speed winding through the action of cam-operated limit switches. On reaching the desired level, the control circuit is disconnected by a cam-operated stop switch, thus releasing the contactors and setting the brake to stop the platform.

For safety in operation, all doors at each level are interlocked to prevent operation unless they are closed. Also, all hatch covers are interlocked to prevent elevator operation unless they are fully opened. The protective features incorporated in the control are (1) slack-cable switches to prevent operation of the elevator if any cable should become slack, (2) emergency stop switches at each level served, (3) over-travel switches to stop the elevator if it should fail to stop at the uppermost level, and (4) overload protection.

Elevator controllers are designed with a double-break feature that prevents maloperation if any one contactor, relay, or switch should fail to function properly. Pushbuttons are interlocked to prevent operation of the elevator unless the platform is at the same level as the pushbutton. Some elevators are equipped with hatchway door mechanical interlocks to prevent opening the door unless the platform is at the same level.

A governor-actuated safety device is provided under the platform to grip the guide rails and stop the platform in the event of overspeed in the DOWN direction. Also, spring bumpers are provided at the bottom of the hatchway to prevent mechanical damage to the hull or platform due to overtravel in the DOWN direction.

Operation

The operation of the elevator depends on the position of the selector switch, which determines between which decks the elevator will run. This switch also renders all master switches inoperative, except those pertaining to the selected levels.

Suppose the selector switch is set in the second paltform to the third deck position (fig. 12-27). In this position the control is set up for the elevator to operate between the second platform and the third deck and closes contacts ①, ②, ④, ⑤, and ⑦. (The third deck is above the second platform.) Contact ② shorts out the first platform stop pushbutton, contact ① places the third deck pushbutton station in the circuit, and contacts ④ and ⑤ short out the first platform DOWN-STOP switches, respectively. Contact ⑦ places the second platform pushbutton station in the circuit.

If the overtravel, slack cable, door switches, stop pushbuttons, and overload relay contacts are in their normally closed positions, the control circuit is energized and set up for operation.

When the second platform UP pushbutton (Fig. 12-27) is momentarily pressed, the UP auxiliary relay, UR, and the UP control relay CRU are energized. This action closes contacts CRU and UR1, which energizes the up contactor, U, in the across-the-line starter. The UP auxiliary relay, UR, also closes contacts UR2, (and opens UR3) which energizes the high-speed contactor, HS. Contactor HS applies voltage to the motor and energizes the brake-release solenoid. The elevator moves upward until it mechanically operates the UP-SLOW limit switch located at the third deck. Operation of the limit switch deenergizes the up auxiliary relay, UR. This action closes contacts UR3 and energizes the LS coil, which transfers the motor from the high-speed, HS, to the low-speed, LS, contactor. The elevator continues upward at low speed until it mechanically operates the UP-STOP limit switch located at the third deck. Operation of the limit switch deenergizes the up contactor, U, which deenergizes the brake-release solenoid and operates the motor brake to stop the motor. An indicating light shows when the elevator reaches the selected deck.

The elevator can be stopped at any time by pressing the stop lever at the pushbutton station located on the selected level, or, in this case, the third deck. To restart the elevator, press the UP pushbutton lever at the second platform or the DOWN lever at the third deck.

In the event of an overload, one of the overload relays will open the control circuit, set the brake, and deenergize the motor. The overload relay must be reset for normal operation by pressing the reset button that projects through the door of the enclosing case.

In the event of supply voltage failure, the line contactors will open and deenergize the motor. To resume operation of the elevator, an UP or DOWN pushbutton lever must be pressed.

As mentioned before, additional protection is provided through a system of series-connected interlocks in the control circuit consisting of door, slack cable, and overtravel switches. If a cable should become slack or if the elevator should overtravel, the elevator can be operated by holding in the SLACK CABLE bypass pushbutton PBS, located inside the controller case. When either one of these pushbuttons is operated, the motor will run only on low speed.

If an overload should occur, the elevator can be operated (in case of an emergency) in the usual manner if the EMERG-RUN lever of either pushbutton station is held in the depressed position.

The up and down current control relays, CRU and CRD, respectively, are provided to ensure proper operation in the event of malfunctioning of other relays or contactors.

ELECTROHYDRAULIC ELEVATOR

The electrohydraulic elevators use hoisting cables and drums in much the same manner as the electric elevator. In this system however, the cable drums are driven through reduction gears by a hydraulic motor.

Raising, lowering or speed changes are accomplished by varying the stroke of the variable delivery hydraulic pump through differential gearing. Figure 12-28 shows a typical arrangement scheme for operation of the electro-hydraulic bomb elevators.

Figure 12-28.—Bomb elevator power plant and control scheme.

Control

The elevators use a followup type control system so that the pump is put on stroke by a pilot motor and the stroke is taken off by the motion of the platform working on the followup control.

On some elevators the pilot motor is started by depressing an operating pushbutton. The pilot motor moves the pump control piston to the ON-STROKE position and the elevator accelerates to full speed. Upon approaching the selected level a platform mounted cam trips a slow-down switch which deenergizes the pilot motor. Movement of the platform then returns the stroke of the pump to the netural position and on reaching the selected level a stop switch deenergizes the brake solenoid to set the brake and stop the elevator.

By reversing the direction of rotation of the pilot motor and hence the direction of movement of the control piston of the pump, the elevator may be moved in the opposite direction.

Another system, where the pilot motor is a d-c motor the speed of which is varied by a rhesotat type control, gives an infinite number of platform speeds ranging from approximately 3 to 90 feet per minute. In installations of this type, a rheostat control is provided on the platform and a duplicate control is provided in the elevator machinery room.

Several methods are used for stroking the pump for emergency operation.

By declutching the "followup" control system from the control stroking unit and manually holding in a pushbutton, thereby releasing the electric motor brake to free the machinery, a handwheel may be used to stroke the pump.

Another method is to rotate the pilot motor armature by attaching a handwheel to an extension on the armature shaft, and thus stroking the pump.

Elevators in some new construction use static controls (no moving parts.) Electronic devices (transistors, SCR's, etc.) perform the functions of previously used relays, contactors, and limit switches.

MAINTENANCE

Adjustments to the machinery and electrical equipment of elevators should be in accordance with the procedures contained in the appropriate manufacturer's instruction books. In addition to these maintenance procedures, the following items should be checked during each shipyard overhaul.

1. Inspect wire cable for wear, corrosion, and broken strands.
2. Check equipment for worn parts and replace those parts that are excessively worn.
3. Inspect and test all safety mechanism to ensure that they are in operable condition.
4. Perform operating tests of the elevator to ensure that it is operating and in satisfactory condition.
5. Check the enclosures of all limit switches (except explosion proof) to be certain that the 1/4-inch drain holes are open to permit draining.
6. Inspect the brake for evidence of excessive wear on the linings and replace as necessary. Adjust the brake in accordance with the manufacturer's instructions. When the brake is adjusted, check the leveling of the platform and correct any inaccuracy in leveling by moving the stop limit switches.
7. Inspect limit switches to determine that the arms are adjusted properly. Adjust each limit switch arm so that approximately one-half of the travel of the arm is taken up by the application of the cam to the switch arm roller. This adjustment will prevent damage to the arm or prevent failure of the switch to operate properly due to the shifting of the platform in the hatchway or movement of the guide rails with the working of the ship's structure.

ELECTROHYDRAULIC STEERING GEAR

The steering gear is one of the most vital auxiliaries aboard ship. It must be thoroughly dependable and have sufficient capacity for maximum maneuverability. The types of steering gear listed in the sequence of their development are the (1) steam, (2) electromechanical, and (3) electrohydraulic types. The electrohydraulic steering gear was developed to meet the excessive power requirements of naval vessels having larger displacements and higher speeds with the attendant increase in rudder torques.

The majority of steering gear installations in new construction naval vessels are of the electrohydraulic type.

CONSTRUCTION

The electrohydraulic steering gear installed in a destroyer (fig. 12-29) consists essentially of a (1) ram unit; (2) power unit; and (3) remote control system (not shown).

Ram Unit

The ram unit is mounted athwartship and consists of a single ram that operates in opposed cylinders. The ram is connected by links to the tillers of the twin rudders and is moved by the oil pressure built up in either of the cylinders, the oil from the opposite cylinder flowing to the suction side of the pump.

The tie rods that connect the two cylinders also serve as guides for a sliding bracket attached to the ram to prevent the ram from rotating. The bracket also provides mechanical limits to the ram travel at 42° of rudder angle. At this position the bracket contacts copper facing on the stop collars and prevents further movement.

A rack is attached to the ram and engages two gears, the rotation of which is transmitted to the respective differential control boxes through the follow-up shaft.

Power Unit

The power unit consists of two pumping systems, which include two motor-driven pumps, a hand pump, two 4-way transfer valves with operating gear, relief valve, two differential control boxes, two "trick" wheels, and a hand emergency gear all mounted on a bedplate, which is the top of an oil reservoir. Steering power is derived from either pumping system acting alone. The system not in use serves as a standby source in case of emergency.

8801111687

27.82

Figure 12-29.—Electrohydraulic steering gear.

The two pumps (port and starboard) are identical in size and design, and are of the variable delivery axial piston type. Each main pump unit includes a built-in vane-type servo pump, pressure control and replenishing valves, and two main relief valves. Each main pump is stroked through a rotary servocontrol.

Each pump is driven by a 20-hp, 1200-rpm, 440-volt, 3-phase, 60-cycle induction motor through reduction gears and a flexible coupling. A disk type electric brake, which is automatically secured when deenergized, is provided on each motor.

The pumps of the power unit are connected to the ram cylinders by a high pressure piping system. The two 4-way transfer valves are interposed in this piping, and their positions determine which pump is connected to the cylinders in the ram unit. The hand lever, which moves both valves simultaneously, is located on the power unit between the "trick" wheels, and has three latched positions. The latched positions are marked P, N, and S, which denote port pump connected, neutral (ram locked), and starboard pump connected, respectively.

The transfer valves, which are of the ported piston type, are mounted on the power unit bedplate between the motors. When the valves are in the neutral (RAM LOCKED) position, the ports of the pipes to the ram cylinders are blocked, and the two pipes from each pump are connected through ported passages in their respective valves. If either or both pumps are started and put on stroke, oil will circulate through the

U.S. C. 1988 1111688

valve and back to the pump. Movement of the transfer valves in either direction connects the selected pump to the ram cylinders, and the opposite pump remains bypassed.

The drain pipes from the ram cylinders lead to the reversible hand pump, which provides a means for emergency steering under limited rudder torques. The relief valve in the emergency steering system is set at 500 psi. The oil flow is through pilot-operated blocking valves that prevent the ram from overhauling the pump and kicking back the handles. When moving the ram with the hand pump, the main transfer valves must be set in the RAM LOCKED position, and the drain valves beneath the cylinders must be open.

The stroking lever and output shaft on each differential control box actuate a rotary servo valve that controls the associated main pump on the power unit. In response to movements transmitted through the control box, the pump discharge is varied between zero and maximum, and in either direction of flow.

In normal steering from the pilot house, a synchro transmitter is turned by the steering wheel. This synchro transmitter is electrically connected to a synchro receiver in the steering gear room. The synchro receiver is geared to the LOWER bevel gear in the differential control unit, and its rotation is transmitted through gearing to a cylindrical cam. A follower roller, which engages a groove in the cylindrical cam, is mounted on an arm keyed to the output shaft of the control box.

For example, assume that the rudder is amidship and it is desired to obtain 20° right rudder. The rotation of the lower bevel gear causes rotation of the cylindrical cam, which, in turn, imparts a motion to the servocontrol valve through the cam roller. This motion of the servocontrol valve puts the pump on stroke. Oil pressure is then applied in the port cylinder, forcing the ram to starboard to give right rudder.

A rack, attached to the ram, rotates the follow-up shaft, which is geared to the UPPER bevel gear in the differential control unit. The movement of the ram and rudders (in response to the stroking of the pump) causes the upper bevel gear to rotate in a direction opposite to that of the lower bevel gear. This action rotates the cylindrical cam in the opposite direction, tending to cancel the movement of the control input and bring the servocontrol valve back to the neutral position to return the pump stroke to neutral and stop the pumping of oil.

Thus, the rudders are at 20° right rudder, the cam is returned to neutral, and the pump is returned to zero stroke until further movement of the steering wheel causes repetition of the cycle. The same sequence occurs if the control is from the trick wheel in the steering compartment.

An engraved dial, graduated in rudder degrees, is mounted on top of the differential control box. Two concentric pointers (one geared to the control pump input and the other geared to the rudder followup) indicate the positions of the helm and rudders, respectively. A helm-angle synchro transmitter, also mounted on the differential control box, actuates a synchro receiver in the steering console in the pilot house. This receiver positions a pointer to indicate to the helmsman the helm angle.

Remote Control System

The remote control system (fig. 12-30) provides control from the pilot house for normal steering. This system consists of a synchro transmitter mounted in the steering console and a synchro receiver mounted on each pump differential control box (port and starboard). A cable selector switch in the pilot house and a similar switch in the steering compartment permit a choice between the port or starboard steering cables. The selection of the control cable is made by the operation of the cable selector switches in the pilot house and in the steering gear room to the desired (port or starboard) position.

The synchro-receiver selector switch in the steering gear room is then set to connect the synchro receiver, on the active power unit, to the steering console synchro transmitter. The rotary motion of the synchro receiver is transmitted through gearing to the input of the differential control box (stroking mechanism) previously described.

The helm angle-indicator synchro transmitters on the differential control boxes in the steering gear room are electrically connected to their associated steering-control synchro receivers. These transmitters under all conditions of operation actuate their associated helm-angle indicator synchro receivers in the pilot house console through their associated cables.

The 120-volt, single-phase power for the remote control system is supplied to the steering power panel through a 450/120-volt

OPI 11589

77.188

Figure 12-30.—Remote control system for steering gear.

11690

transformer from the steering power transfer switchboard. The 120-volt, single-phase power for the indicator synchro transmitters is supplied from the I. C. switchboard through circuits L (rudder order system) and N (rudder angle indicator system).

Magnetic Controller

The motor of each steering gear pump is provided with a nonreversing across-the-line starter and a maintained-contact master switch (fig. 12-31). The starter is supplied with 440-volt, 3-phase, 60-cycle power from the steering power transfer switchboard located in the steering engineroom.

The pump motor on either power unit is started or stopped by operating the maintained-contact pushbutton, on the associated pushbutton station, to the desired position. When the maintained-contact start pushbutton is pressed, the circuit is completed to the operating coil, M, of the line contactor. This action energizes the operating coil and closes the contactor in the motor starter to connect the motor to the line. The motor will continue to run until the contactor operating coil, M, is deenergized because of loss of voltage, tripping of the overload relay, or by pressing the stop pushbutton.

The motor starter is provided with overload and low-voltage release protection. The overload relays are of the thermal type, similar to those installed in the previously described anchor windlass starter. The low-voltage release protection is provided by use of the maintained-contact master switch.

If the operating coil, M, is deenergized due to failure of the line voltage or tripping of an overload relay, the contactor will reclose and restart the motor when voltage is restored or when the overload relays are reset by means of the reset pushbutton.

In an emergency the motor can be run (even though the overload relays have been tripped) by holding the EM-RUN pushbutton closed with the start pushbutton in the operated position. If the overload condition has not been corrected, the motor will operate only as long as the EM-RUN pushbutton is held closed.

OPERATION

The steering gear is normally secured with the rudders amidship and with the transfer valve shift lever in the neutral (N) position, which hydraulically locks the ram and rudders.

To operate the port power unit, using the port steering cable:

1. Set the valves and plug cocks of the hydraulic system in accordance with the operating diagram for the steering gear for normal power operation.
2. Set the transfer valve shift lever in the neutral (N) position.
3. Press the start pushbutton to start the port pump motor.
4. Engage the trick wheel and turn it until the helm indicator (pointer) corresponds with the rudder angle indicator.
5. Move the transfer valve shift lever to the PORT (P) position to connect the port pump unit to the ram.
6. Close the port and starboard circuit breakers on the 120-volt steering power panel to energize the synchro receiver selector switch and the cable selector switch in the steering gear room.
7. Turn the synchro-receiver selector switch and the cable selector switch (in steering gear room) to the PORT positions.
8. Turn the cable selector switch (in pilot house) to the PORT position to energize the remote control synchro transmitter to steer from the bridge.
9. Disengage the trick wheel on the port unit and engage the trick wheel on the idle (starboard) unit.

To shift from the port power unit, using the port steering cable, to the starboard power unit, using the starboard steering cable:

1. Press the start pushbutton to start the starboard (idle) pump motor.
2. Notify the pilothouse to keep wheel motionless during change of units.
3. Allow rudder angle indicator to line up with helm indicator; then operate the transfer valve shift lever to the starboard (S) position to connect the starboard pump to the ram. Transfer the remote control from the port to the starboard unit by operating the synchro-receiver selector switch (in steering gear room).
4. Transfer the cable selector switch (in steering gear room) and cable selector switch (in pilot house) to the STARBOARD positions.
5. Disengage trick wheel and steer from the bridge.
6. Press the stop pushbutton to stop the port motor and engage the trick wheel on this unit.

11691

77.189

Figure 12-31.—Nonreversing across-the-line starter for steering gear pump motor.

To steer from the trick wheel:

1. Select the power unit to be used and follow the procedures described previously for operating the port power unit.

2. Engage the trick wheel of the selected power unit.

3. Deenergize the remote control system by operating the synchro-receiver selector switch in the steering gear room to the OFF position.

4. Steer the ship as directed from the bridge.

To operate by hand emergency steering:

1. Set the valves and plug cocks of the hydraulic system in accordance with the operating diagram for the steering gear for hand steering.

2. Set the transfer valve shift lever in the NEUTRAL (N) position.

3. Crank the hand pump in the proper direction until the desired rudder angle is obtained.

When the hand pump is used for emergency steering, the ship's speed and rudder angles must be controlled so that the pressures in the ram cylinders will not exceed the setting of the relief valve, which is installed in the emergency steering system.

To secure the steering gear when steering under power operation:

1. Request the pilothouse to put rudders on zero angle or use the trick wheel for this purpose.

2. Operate the transfer valve shift lever to the NEUTRAL (N) position.

3. Deenergize the remote control system by turning the synchro-receiver selector switch and the cable selector switch (in the steering gear room) and the cable selector switch (in the pilot house) to the OFF positions. Open the port and starboard circuit breakers on the 120-volt steering power panel.

4. Stop the pump motor by pressing the associated STOP pushbutton.

The maintenance of the steering gear must be in accordance with the instructions contained

11692

in the manufacturers' technical manuals for the equipment installed aboard your ship.

ELECTRIC GALLEY EQUIPMENT

Electric galley equipment comprises the heavy duty cooking and baking equipment installed aboard naval vessels and consists essentially of ranges, griddles, deep fat fryers, roasting ovens, and baking ovens (fig. 12-32). This equipment is supplemented by electric pantry equipment, which includes coffee urns, coffee makers, griddles, hotplates and toasters. The number and capacity of the units comprising a galley installation depends on the size and type of ship. Galley equipment is normally designed for operation on 115-volt or 230-volt, d-c power or 440-volt, 3-phase, 60-cycle, a-c power. A type A range is illustrated in figure 12-32A. A roasting oven is pictured in figure 12-32B, and a deep fat fryer) is shown in figure 12-32C.

48.8-.11

Figure 12-32.—Electric galley equipment.

RANGES

Electric galley ranges are provided in type A (36-inch), type B (20-inch, and type C (30-inch). The ranges consist of a range-top section and an oven section assembled as a single unit, and a separate switchbox designed for overhead or bulkhead mounting (fig. 12-32, A).

The RANGE TOP SECTION (type A range) is provided with three 6/R-kw surface units consisting of combination griddle hotplates with cast-in, enclosed heating units or with enclosed heating units fastened to the underside. The surface units are individually controlled by a high temperature thermostat, the bulb of which is covered and clamped to the underside of the griddle hotplate. Each thermostat is connected in series with the operating coil of an associated heavy-duty contactor. When the thermostat contacts close, the contactor coil is energized and closes the contactor to energize the heating unit. The thermostat controls for the surface units are located on a panel at the front of the range-top section.

The OVEN SECTION is provided with two 3-kw enclosed heating units, one located in the top and one in the bottom of the oven compartment. The oven units are separately controlled to regulate the relative temperature at the top and bottom of the oven by individual 3-heat rotary switches located in the overhead switch-box. The oven is also provided with an adjustable temperature control (thermostat) to establish the average temperature that is to be maintained in the oven. The thermostat control for the oven units is located on a panel at the right of the oven.

A compartment at the right of the oven contains a terminal board for making the connections between the range and the switchbox. The compartment is equipped with a removable cover for access to the interior.

The SWITCHBOX consists of a sheet-steel enclosure provided with a hinged or removable cover for access to the interior and a panel on which are mounted the two oven switches. The switchbox houses the cutout blocks, fuses, contactors, and the line terminal block. A

OVENS

The type 4 and type 6 baking ovens are the older type having baking decks (the type number denotes the number of decks) that are not thermally insulated from each other. The heating units are located at the top and bottom of the oven and between each deck. Each heating unit is controlled by individual 3-heat switches located in a switch box enclosure mounted on the right-hand side of the oven.

The type 12 and type 18 baking ovens are sectional type ovens with each section consitituting a separate oven that is thermally insulated and operated independently of the other sections. Each section of the type 12 or type 18 ovens has a capacity of six standard five-loaf bread pans. The type 12 oven consists of two sections and the type 18 oven consists of three sections mounted one above the other. The type numbers denote the total bread pan capacity of the oven.

Type 60 and type 125 roasting ovens are sectional type ovens with each section constituting a separate oven that is thermally insulated and operated independently of the other sections (fig. 12-32, B). The type number denotes the capacity in pounds of raw meat per section. The roasting ovens are provided in either 2 or 3 sections mounted one above the other.

The type 12 and type 18 baking ovens have the same general construction of the type 60 and type 125 roasting ovens except that the oven compartments of the roasting ovens are about four inches higher. Each oven section of both the baking and roasting ovens is provided with two heating units, one located in the top and one in the bottom (underneath the deck) of the oven compartment. The heating units are usually of the enclosed type but some ovens have open-coil type heating units consisting of resistance wire wound on reinforced porcelain rods that are mounted in a steel frame. The oven units are controlled by individual 3-heat rotary switches (two for each section). Each oven section is also provided with an adjustable thermostat for automatic control of the average temperature. The operation of the 3-heat switches and the temperature control is the same as for the type A range previously described.

The type 60 and type 125 roasting ovens are provided with a separately mounted switch box which contains the fuses, contactors, and 3-heat switches for each section. Figure 12-34 is a wiring diagram of the type 60 oven. The types 12 and 18 baking ovens do not have a separate switch box because all control devices are mounted in a compartment at the right of each oven. The compartment is provided with a hinged, or removable, cover for access to the interior.

DEEP FAT FRYERS

Electric deep fat fryers, are normally provided in the type 23, type 45, and type 90 sizes rated at 5 kw, 10 kw, and 18 kw, respectively. The fryer consists of a rectangular sheet-steel enclosure that houses a polished-steel fat container (fig. 12-32, C). The fat container is rectangular and is equipped with a drain valve for draining the fat.

The heating units, which are of the enclosed type, are immersed directly in the fat to ensure maximum efficiency. The fryer is equipped with an adjustable automatic temperature control to maintain the fat at the desired temperature. The thermostat control, located on a panel at the front of the fryer, is provided with an OFF position and the adjustable temperature range of 250°F to 40°F is graduated on the control knob.

The thermostat operates contactors, which, in turn, control the circuits to the heating units. The later models of type 45 and 90 fryers are equipped with an upper temperature limit thermostat which operates in the event of failure of the main thermostat. The contacts of the upper limit thermostat are connected in series with a 25-ohm, 25-watt resistor and in parallel with the operating coil of the main power contactor. In the event the temperature reaches 460 degrees F., the thermostat contacts will close, blow a 1-ampere fuse in the control circuit, and de-energize the fryer.

A rotary switch also located on the front panel is provided for disconnecting the fryer from the line. As a safety measure, the switch should be turned to the OFF position when the fryer is not in use.

A compartment located inside the fryer contains the contactors, thermostat, heating unit terminals, line terminal block, fuses, and line switch. The compartment is equipped with a removable panel for access to the control devices. Figure 12-35 is a simplified wiring diagram of the type 90 fryer.

MAINTENANCE

Before starting any service work on electric galley equipment be certain that the equipment is disconnected from the power supply. Electrical circuits in the equipment should be inspected and tested at least once each month.

Refer to the manufacturers' manuals for instructions concerning the servicing of the electric galley equipment installed aboard your ship. These manuals also include the methods of removing and replacing the various heating units, thermostats, switches, contactors, and other components of electric cooking equipment.

77.193

Figure 12-35.—Wiring diagram of type 90 fry kettle.

CHAPTER 13

GYROCOMPASSES

The gyrocompass has been standard equipment on all naval ships since the early part of the century. There are two principal types of gyrocompass in use, one manufactured by Sperry Rand Corporation, the other by American Bosch Arma Corporation.

Gyrocompasses are identified by the Mark-Mod system. The mark (Mk) number designates a major development of a compass, the modification (Mod) number shows a change to the major development. The Navy currently uses seven marks of Sperry and six marks of Arma gyrocompasses.

There have been various modifications to most marks of both types. Some are still being modified and new marks are under development to meet the needs of modern ships.

The early gyrocompasses were used exclusively for navigational purposes, and an accuracy of plus or minus one degree was considered satisfactory. Today, however, the need for accuracy is much greater, as the gyrocompass supplies ship's course inputs to various systems such as complex fire control and missile systems, radar and sonar systems, plotting and dead-reckoning equipment.

Some of the latest gyrocompasses also furnish roll and pitch data, continuously indicating the zenith as well as the meridian.

Basically, all gyrocompasses depend upon four natural phenomena for their operation. The first two are inherent properties of the gyroscope called gyroscopic inertia and precession. The third and fourth relate to the earth's rotation and gravitation. It is only in the methods whereby these phenomena are utilized that we distinguish one type of gyrocompass from another.

This chapter will discuss these phenomena, and show how a free gyroscope is adapted to a gyrocompass, using the Sperry Mk 11 Mod 6 gyrocompass as a representative compass.

FREE GYROSCOPE

If a heavy wheel rotating at high speed is supported in rings, as shown in figure 13-1, it becomes a true gyroscope. The supporting rings provide three mutually perpendicular axes which allow the spin axis of the wheel to point in any direction. For this chapter's discussion, the axes will be referred to as the spin axis, horizontal axis, and vertical axis. The assembly is balanced about all three axes.

A gyroscope has two fundamental properties upon which all of the applications of the devices are based. These two characteristics are known as GYROSCOPIC INERTIA and PRECESSION.

GYROSCOPIC INERTIA

Gyroscopic inertia, stability, or rigidity of plane as it is sometimes called, is that property

27.127

Figure 13-1.—The gyroscope has three axes of angular freedom.

of a gyroscope which makes it try to keep the spin axis parallel to its original position. This property is explained by Newton's first law of motion which states that a body in motion will continue to move at constant speed in a straight line unless it is acted upon by an outside force. Any point on a spinning wheel is moving in a circular path. Because of inertia (Newton's first law), such a point will tend to move in a straight line, tangent to its circular path. But molecular attraction within the wheel holds the particles together and confines all the particles in the wheel to circular paths. (However, any wheel will fly apart if it is spun with sufficient speed.) Although each particle is confined to a circular path, the entire wheel is free to change its plane; but because each particle tends to stay in a straight line, the inertia of every particle causes it to resist leaving that plane. Thus the rotating wheel tends to rotate in the same plane and to resist any force which tries to change its plane of rotation. In figure 13-2 consider the particles in the rotor at points a, b, c, and d. A momentary force, F, exerted on the axle attempts to change the direction of the path of points c and d—that is, point c tends to move upward and point d downward. Because of the very high kinetic energy, these points resist any attempt to change their paths or directions of motion. The energy and momentum of the rotor attempts to keep the plane of the rotor and the alignment of the axle fixed in space. Gyroscopic inertia may be illustrated by slowly tipping the base of the gyroscope as shown in figure 13-3. With the rotor spinning, the ZZ^1 axis will remain horizontal. The rotor will continue to maintain its original plane of rotation no matter how much the base of the gyro is tipped about the X axis, as long as it continues to spin with sufficient velocity.

Gyroscopic inertia depends upon angular velocity, weight of the rotating mass, and radius at which the weight is concentrated. Maximum effect is obtained, therefore, from a weight rotating at high speed with its principal weight concentrated near the rim.

77.195

Figure 13-2.—Spinning rotor with a vertical axle.

PRECESSION

Precession is that property of a gyroscope which causes the spin axis to change direction when subjected to any force that tends to change its plane of rotation. Because of gyroscopic inertia, it has been shown that moving the outer supporting frame has no effect on the direction in which the axle of a spinning gyroscope points. To change this direction, it is necessary to apply a force to the gyroscope rotor or its axle. A horizontal force, F, on one end of the axle (fig. 13-2) produces a turning effect which attempts to tilt the gyroscope about the axis ab in the direction of arrow g. If the rotor were not spinning, the axle would tilt in that manner. When the rotor is spinning, however, its rigidity causes it to resist any attempt to tilt the axle about ab and instead it turns about the axis cd in the direction of arrow e. Conversely a force attempting to turn the gyroscope about the axis cd is similarly resisted and results in a tilt about the axis ab. If the force is applied in direction H, rotation will occur in the direction of arrow-g.

This rotation of a gyroscope about an axis perpendicular to the axis about which a force is exerted is called PRECESSION. Precession takes place whenever any force tends to tilt the axle of a spinning gyroscope rotor. The precession caused by the applied force is always about an axis at right angles to the axis about which

00711699

27.128
Figure 13-3.—Rigidity of plane of spinning gyroscope.

27.129
Figure 13-4.—Precession about the vertical axis.

the force is applied. A simple way to remember the direction in which precession takes place is to regard the force F as though it acted at a single point on the rim of the wheel (in at point X, figure 13-4). This point will not move in response to force F, but a point 90 degrees beyond, in the direction of the wheel's rotation, will move away instead. Thus the gyro in figure 13-4 will precess about its vertical axis in the direction indicated by arrow P.

Any force that tends to change the plane of rotation causes a gyroscope to precess. Precession continues as long as there is a component of force acting to change the plane of rotation; and precession ceases immediately when the force is removed. If the direction in which the force is acting remains unchanged, the gyroscope precesses until the plane of the rotor contains the force's line of action. When this position is reached, the force is about the spinning axis and can cause no further precession.

If the line in which the force acts moves at the same rate and in the same direction as the precession which it causes, the precession will be continuous. This is illustrated by figure 13-5, in which the force attempting to change the plane of rotation is provided by a weight W suspended from the end of the horizontal axle. Although the weight is exerting a downward force, it must be remembered that the force it produces against the particles in the spinning wheel is horizontal. This force is imparted to the particles in the wheel as exemplified by arrows F and F^1. If the wheel rotates clockwise as seen

ee11700

77.197

Figure 13-5.—Continuous precession.

from the weighted end, precession will occur in the direction of arrow P. As the gyroscope precesses, it carries the weight around with it so that forces F and F^1 continuously act at right angles to the plane of rotation and precession continues indefinitely.

A valid explanation of why precession occurs requires the use of vector representations of torques and angular motions and is beyond the scope of this text. However, the concept of torque should be understood since that term is used extensively in the discussion of gyrocompasses.

Torque is defined as the product of a force which tends to produce rotation and the perpendicular distance from the line in which that force is acting to the axis about which the rotation tends to occur. Whereas force acts in a straight line at or on a point, torque occurs in a plane, and is referred to as being applied about an axis. A force acting on the axle of a gyroscope produces a torque about either, or both of the gyro's other two axes. For a given amount of force, the greater its distance from the axis of rotation, the greater the torque. If the force is acting on the axis of rotation, the torque is zero (F X 0 = 0).

FORCE OF TRANSLATION

Any force operating through the center of gravity of the gyroscope does not change the angle of the plane of rotation but moves the gyroscope as a unit without changing its position in space. Such a force operating through the center of gravity is known as a FORCE OF TRANSLATION. Thus, the spinning gyroscope may be moved freely in space by means of its supporting frame, without disturbing the plane of rotation of the rotor. This condition exists because the force that is applied through the supporting frame acts through the center of gravity of the rotor and is a force of translation. It produces no torque on the gyro rotor.

EFFECT OF EARTH'S ROTATION

As explained previously, a free-spinning gyroscope can be moved in any direction without altering the angle of its plane of rotation. If this free-spinning gyroscope is placed on the earth's surface at the equator with its spinning axis horizontal and aligned east and west, an observer in space below the south pole would note that the earth rotates clockwise from west to east and carries the gyroscope along. As the earth rotates, rigidity of plane keeps the gyroscope wheel fixed in space and rotating in the same plane at all times. Figure 13-6 shows how this gyroscope would appear to the observer in space. Assume that the gyroscope is set spinning at 0000 hours with its spinning axis aligned east and west and parallel to the earth's surface. At 0600, 6 hours after the gyroscope was started, the earth has rotated 90° and the axle of the gyroscope is aligned with the original starting position. At 1200 the earth has rotated 180° while the gyroscope retains its original position.

11701 10711

27.132

Figure 13-6.—A gyroscope with its spin axis set in the east-west position at the equator, observed from a point in space beyond the south pole. (Horizontal earth rate.)

At 0000 the earth has rotated 360° and the gyroscope is back in its original position.

This rigidity of plane appears quite different to an observer on the earth's surface. As the earth rotates, the observer moves with it and the gyroscope wheel appears to rotate about its horizontal axis. By rotating the page counterclockwise and observing the successive pictures of the gyro as they come to the top of the figure, the changes as seen by the observer on the earth's surface become readily apparent. Note that if the gyro had been originally set with its axle pointing north and south, there would be no effect apparent to the observer. This apparent rotation or tilt of the gyro horizontal axis is referred to as HORIZONTAL EARTH RATE effect. This effect varies with the cosine of the latitude, and is maximum at the equator and zero at the poles.

Now assume that the spinning gyroscope, with its spinning axis horizontal, is moved to the North Pole (fig. 13-7). To an observer on the earth's surface the gyroscope appears to rotate about its vertical axis. To an observer in space the gyroscope axle appears to remain fixed and

27.133

Figure 13-7.—A gyroscope with its spin axis set horizontal at the north pole, observed from a point in space beyond the equator. (Vertical earth rate.)

the earth appears to rotate under it. This apparent rotation about the vertical axis is referred to as VERTICAL EARTH RATE effect, and varies with the sine of the latitude. It is maximum at the poles and zero at the equator.

APPARENT ROTATION OF THE GYROSCOPE

The rotation of the gyroscope axle as seen by the observer on the earth's surface is known as APPARENT ROTATION. Apparent rotation is caused by rigidity of plane which tends to

11702 10711

maintain the plane of the gyroscope wheel parallel to its original position in space.

In general, the horizontal earth rate causes the gyro to tilt and the vertical earth rate causes the gyro to move in azimuth with respect to the earth. If it is recalled that the apparent motion of the stars through the sky is a counterclockwise rotation about the North Star, a convenient reminder of the effect of the earth's rotation on a free gyroscope is to consider the gyro axle pointing at a star. The axle will continue to point at the same star (since the stars are fixed in space) and will describe a circle about the North Star. Thus the difference between gyroscopic inertia and apparent rotation is simply one of point of view. As far as space is concerned, the gyro remains fixed; with respect to the earth, however, the gyro actually rotates as described above. As will be seen later, it is this rotation of the gyro with respect to the earth which makes it possible to apply the force of gravity so as to convert the free gyroscope into a north-seeking gyrocompass.

When the gyroscope axle is placed parallel to the earth's axis at any location on the earth's surface, the apparent rotation is about the axle of the gyroscope and cannot be observed. At any point between the equator and either pole, a gyroscope whose spinning axis is not parallel to the earth's spinning axis has an apparent rotation that is a combination of the apparent rotation at the pole and at the equator. This apparent rotation is about both the horizontal and the vertical axes. Apparent rotation is illustrated by placing a spinning gyroscope with its axle on the meridian (aligned north-south) and parallel to the earth's surface at 45° north latitude and 0° longitude, as shown in figure 13-8. As the earth rotates, the positions of the gyroscope at 0000, 0600, 1200, and 1800 show the apparent rotation about the vertical and horizontal axes. Both views are of the same gyroscope, but they are from different angles in order to show the movement about both axes. In both views the observer is above the earth's surface, but he is rotating with the earth. Both views should be considered together because they show the same movement although in different planes.

A and B of figure 13-8 show the spinning gyroscope at 0000. The axle is on the meridian and is parallel to the earth's surface. The apparent movement of the gyroscope at 0600 (C and D of fig. 13-8) is due to the rotation of the earth. The gyroscope axle has moved from alignment

77.199

Figure 13-8.—Apparent rotation of a gyroscope at 45° N latitude.

with the meridian to a position 45° east of the meridian, and the axle apparently has tilted 45° from the horizontal. At 1200 (E and F of fig. 13-8) the gyroscope axle has moved back to the meridian, but it is tilted now at an angle of 90° from the horizontal. At 1800 (G and H of fig. 13-8) the axle has swung 45° west of the meridian, and the tilt of the axle has decreased 45°. After 24 hours, at 0000 the next day, the axle is back on the meridian and is horizontal (A and B of fig. 13-8). The action of any free gyroscope at any latitude between 0° and 90° is similar. This apparent rotation is caused by the earth's rotation.

A gyroscope, if set on any part of the earth's surface with the spinning axle not parallel to the earth's polar axis, appears to rotate, over the center of the gyroscope and parallel to the

earth's axis. This apparent rotation is in a counterclockwise direction when viewed from south to north. The path that the north axle describes in space is indicated by the circle EAWB back to E (fig. 13-9).

The effect of the earth's rotation causes the north end of the gyroscope axle to rise when east of the meridian and to fall when west of the meridian in any latitude. This tilting effect provides the means by which the gyroscope can be made into a north-seeking instrument.

CONVERTING A GYROSCOPE INTO A GYROCOMPASS

Before a free gyroscope can be converted into a gyrocompass the mounting structure must be changed slightly for reasons which will be discussed later in this chapter. As shown in figure 13-10, the rotor is mounted in a sphere and the sphere is supported in what is called the VERTICAL RING. The sphere and vertical ring are, in turn, mounted in a base called the PHANTOM. At this point in the discussion, assume that the vertical ring and phantom are made to follow the gyro about the vertical axis as it turns in azimuth.

With no further additions, the gyroscope shown in figure 13-10, is still a free gyro. To make a gyroscope into a gyrocompass, the gyroscope has to be made to seek and maintain a true north indication. Since north is the direction represented by a horizontal line in the meridian plane from the point of observation to the North Pole, some means must be provided to: (1) make the gyro axle seek the meridian (point to the North Pole) and (2) keep the axle horizontal.

SEEKING THE MERIDIAN

At the equator, a free gyroscope, if set with its spinning axle horizontal and parallel to the earth's axis, remains in that position because the apparent rotation produced is about the gyroscope axle. Thus, it becomes a direction-indicating device. Once set, it continues to point north as long as no disturbing forces cause it to precess out of the plane of the meridian. Such an instrument, however, is not useful as a compass because any slight friction sets up torques that cause it to precess away from the meridian. Except at, or near, the equator an excessive tilt in relation to the earth's surface is required to keep the gyroscope axle parallel to the earth's axis. In high north or south latitudes,

77.200

Figure 13-9.—Path of the spinning axle of a free gyroscope.

11704

27.135

Figure 13-10.—Modified model gyroscope.

if the axle is set sufficiently level for the instrument to be useful as a compass, the earth's rotation causes it to turn away from the meridian, as illustrated in figure 13-8.

The first step in making a gyroscope a gyrocompass is to make the gyro seek the meridian. To do this, a weight W is added to the bottom of the vertical ring, as shown in figure 13-11. This causes the vertical ring to be pendulous about the horizontal axis.

27.136

Figure 13-11.—Making the gyroscope seek north by the addition of a weight to the vertical ring.

The manner in which weight W causes the axle to seek north is shown in figure 13-12, A through E. Assume the gyro to be at the equator with axle horizontal, pointing east-west. This represents the "worst case", or maximum deviation from the desired end result of the axle pointing north-south. Also assume the wheel to be spinning clockwise when viewed from the west. At point A, in figure 13-12, the gyro and vertical ring are vertical and no torque is created by the added weight. At this point both properties of the gyroscope, gyroscopic inertia and precession, are brought into play. As the earth rotates, the axle and therefore the vertical ring become inclined to the horizontal as shown at B in figure 13-12. The weight W is raised against the pull of gravity and consequently causes a torque about the north-south axis of the gyro. This torque causes precession about the vertical axis in the direction indicated at C in figure 13-12; the gyro then has moved out of its original east-west position.

As the end of the gyro which was first pointing east (which will now be referred to as the north end) continues to rise, the torque on the gyro caused by the weight becomes greater since the moment arm through which the weight acts gets longer due to the greater tilt. Since the speed of precession is closely proportional to the tilt, the gyro turns about the vertical axis as shown at D in figure 13-12 (in azimuth) at an increasing speed until the axis is on the meridian (E in fig. 13-12).

At the meridian, the tilt, the torque caused by the weight, and speed of precession are all at a maximum. It should be noted here that it is the righting couple applied to the tilted axle by the pendulous weight which causes the compass to precess past the meridian, the kinetic energy of precession being entirely negligible. After the north end of the gyro axle crosses the meridian, the higher (north) end of the tilted axle is to the west of the meridian. As a result, referring back to figure 13-8, the earth's rotation reduces the tilt. As the tilt becomes less, the speed of the precession in azimuth decreases. Finally the axle becomes horizontal and precession to the west stops; the weight on the vertical ring causes no torque about the horizontal axis since it is hanging straight down. At this point, the axle has precessed as far west of the meridian as it was east originally.

As the earth continues to rotate, the north end of the axle starts to dip. The weight W is raised on the opposite side of the horizontal

11705

27.137

Figure 13-12.—Effect of the weight and earth's rotation on the gyroscope.

axis in the opposite direction to what it was originally. Precession takes place in the opposite direction carrying the gyro axle back across the meridian to its original position. At this point, the cycle is repeated and will go on indefinitely. The oscillation about the meridian may be understood by referring to F in figure 13-12 which shows the movement of the gyro axle projected on a vertical plane. The ellipse in figure 13-12F is the result of a displacement of the gyro axle only a few degrees from the meridian. If the gyro axle were pointing east-west of the beginning of the cycle as shown at A in figure 13-12, precession would take place through 180 degrees in each direction, and at one extreme the axle would point east, at the other, west. In any case, the gyro never comes to rest since there is no force tending to restore the axle to the horizontal position until it has passed the meridian.

The ratio of the movement about the horizontal axis (caused by apparent rotation) to the precessional movement about the vertical axis caused by the swing of the weight determines the shape of the ellipse. If the weight is increased, the speed of precession will increase and the ellipse will be flatter. If the weight is decreased, the speed of precession will decrease and the ellipse will diminish to a point where the ellipse would, theoretically, be almost circular. The time, in minutes, required for one complete oscillation is called the period of oscillation. For any given wheel and speed at a certain spot on the earth, the period will be

11706

nearly the same regardless of the angle through which the wheel oscillates. The period can be changed by changing the amount of weight on the bottom of the vertical ring.

With such a gyroscope modified by hanging a weight on the vertical ring, the first condition required to make a gyroscope into a gyrocompass, that of making the gyro axle seek the meridian, has been fulfilled. However, some means must be provided for suppressing the oscillations so the gyro wheel will quickly come to rest with its axle level in the north-south position.

SETTLING ON THE MERIDIAN

To suppress the oscillations of the gyro about the meridian a small weight W_1 (fig. 13-13) is added to the sphere in which the gyro is housed. This weight is placed on the east side of the gyrosphere for the gyro rotates clockwise when viewed from the south. With the gyro axle level, the torque produced by gravity acting upon the weight W_1 is restrained by the vertical axis bearings. When the gyro axle tilts because of earth rate, the vertical axis is no longer vertical; the force of gravity, however, still pulls straight down on the weight. This allows the torque to act about the vertical axis.

Now, with both weights, the gyro will begin to tilt because of earth rate and as soon as it tilts, the gyro precesses in azimuth toward the meridian and downward toward the level position. As a result of the leveling action of weight W_1, the gyro axle is not tilted up as much when it reaches the meridian as it was with only weight W. Since the gyro axle is not tilted as much, the torque produced by weight W is not as great. Therefore, the gyro axle will not precess as far to the west of the meridian as it was east of the meridian when it was started.

After reaching a point where the axle is level and as far west of the meridian as it is going due to the action of weight W, earth rate is still causing the axle to tilt downward. As a result, torques are created which precess the gyro to the east and up. The same action takes place in the reverse direction. The gyro, this half of the cycle, is not precessed as far to the east as it was to the west. Thus, the added weight W_1 causes the ellipse to be reduced each successive oscillation; the north end of the gyro axle will follow a spiral path as shown in figure 13-14 instead of an elliptical path as previously described.

A careful consideration of the action of the two weights will make it apparent that the only position of rest that the gyro can find will be with the gyro axle horizontal and on the meridian. In other words, the free gyroscope has been converted into a true meridian-seeking gyrocompass. The period of the compass can be changed by varying the weight W, and the speed with which it settles to a level position can be changed by varying the weight W_1.

Figure 13-13.—Modified model gyroscope with weights on the vertical ring and sphere.

GRAVITY REFERENCE SYSTEMS

Three types of compasses are used by the Navy. They differ mainly in the manner in which they utilize the force of gravity to cause the desired precession. The NONPENDULOUS type of compass, manufactured by Sperry Gyroscope Company, Inc., uses a device called a liquid ballistic; whereas the PENDULOUS type of compass manufactured by Arma Corporation has more of the weight of the rotor and case below the center of support, making it in effect pendulous. The Sperry Gyroscopes Mks 19 and 23 use neither a liquid ballistic nor a pendulous type of gravity reference system. Instead, they use an electrolytic level to develop an electric signal, which is amplified and converted to torque electromagnetically. The electrolytic level generates a signal voltage that is proportional to the tilt of the gyro axle. This signal

11707

27.139

Figure 13-14.—Effect of both weights on the gyroscope.

is amplified, then fed to the torquers which provide the necessary torques to make the compass seek and settle on the true meridian.

SPERRY PRINCIPLES

Sperry gyrocompasses (with the exception of the Mks 19 and 23) employ a mercury ballistic, or liquid ballistic in the case of the Mk 22, which provides necessary torques to make the compass continuously seek the meridian (true north).

Mercury Ballistic

In its simplest form, the mercury ballistic consists of two mercury-containing reservoirs, one mounted at each end of the rotor axle. The two reservoirs are connected by a pipe so that the mercury is free to flow from one reservoir to the other, as shown in figure 13-15.

When the axle is level (fig. 13-15A), the reservoirs contain the same amount of mercury, weigh the same, and exert the same downward force each on the end of its axle. Therefore, no torque is produced about any axis. When the axle is tilted, even slightly (fig. 13-15,B), mercury runs through the connecting tube from the higher container to the lower container. The amount of mercury in the two tanks is no longer equal. The lower tank is heavier because it contains more mercury. Therefore, the lower tank exerts more force against its axle than does the upper tank, and produces a torque about axis H-H'. This torque, which seemingly

11708

77.201

Figure 13-15.—Action of a mercury ballistic.

tends to increase the tilt, instead, causes precession about the vertical axis, V-V'.

The rotor in a Sperry gyrocompass spins counterclockwise when viewed from the south end of the axle. When the north end is low, the excess mercury in the north tank exerts a downward pressure on the north end of the axle and causes precession to the east, or clockwise. When the north end is high the excess mercury in the south tank exerts a downward pressure on the south end of the axle and causes precession to the west, or counterclockwise.

As you have learned, when the north end of the rotor axle is east of the meridian, the earth's rotation causes it to rise. When a mercury ballistic is added to the gyroscope, the elevation of the north axle produces a torque about the horizontal axis that causes counterclockwise, or westerly, precession. When the north end of the axle is west of the meridian, the earth's rotation causes it to drop. A low north axle causes the mercury ballistic to exert a torque about the horizontal axis that gives clockwise, or easterly, precession.

If this gyroscope with its mercury ballistic is set on the equator with the axle pointing to the east of the meridian and with the rotor spinning counterclockwise (fig. 13-16,A) the north end of the axle tilts upward because the

77.202

Figure 13-16.—Elementary Sperry gyrocompass at the equator.

earth rotates under it. When this tilt occurs mercury flows from the north to the south tank, and the south tank becomes the heavier. The south tank applies a torque around the horizontal axis (fig. 13-16, B). This torque results in a precessional motion around the vertical axis toward the meridian and the west. Because the earth is constantly turning, the gyroscope continues to tilt upward, more mercury flows to the south tank, and the torque around the horizontal axis gradually increases with a corresponding increase in the precession about the vertical axis (fig. 13-16, C & D). This upward tilting continues until the gyroscope axle is on the meridian (fig. 13-16, E). The south tank contains more mercury than the north tank, and the gyroscope is tilted upward its greatest amount. At this point the rate of precession is at its peak.

After the gyroscope axle crosses the meridian it begins tilting downward so that mercury flows from the south tank to the north tank. This transfer of mercury gradually reduces the torque about the south end of the axle with a corresponding gradual reduction in the rate of precession of the gyroscope about the vertical axis. When the gyroscope axle is once more level, it points to the west of the meridian, the mercury is distributed equally in both tanks, no torque is applied to either the north axle or the south axle, and precession ceases.

As the earth continues moving, the north end of the gyroscope axle tilts downward, and mercury flows into the north tank, which applies a torque to the north end of the spin axis. Hence, the direction of precession is reversed and is now toward the east. The downward tilt of the

11709

spinning axis continues, and the torque and rate of precession increase. By the time the gyroscope axle reaches the meridian, it has attained its maximum rate of precession again, but it now has a downward tilt. After the gyroscope passes the meridian, the rotation of the earth starts the north end of the gyroscope axle tilting upward. As this action occurs the torque about the north axle gradually diminishes to zero and the precessional motion around the vertical axis slows down until the gyroscope axle is once more horizontal and precession ceases. When the gyroscope axle becomes horizontal, the axle points in its original starting position. Figure 13-17 shows that the path followed by the north axle of the gyroscope has the shape of an ellipse. The gyroscope continues these oscillations indefinitely as long as the wheel is spinning.

ARMA PRINCIPLE

The Arma compass is north-seeking because it is given a force of precession by a pendulous weight. To understand how this compass operates, assume again that the gyroscope is on the equator and that its spinning axis is horizontal and points to the east of the meridian. Instead of having a mercury ballistic, the gyroscope has a weight, W, at the bottom of the rotor case, as shown in figure 13-18. The north end of the gyroscope appears to tilt upward because the gyroscope wheel maintains its plane in space as the earth revolves under it. Gravity attracts the weight toward the center

77.203
Figure 13-17.—Undamped period of the Sperry compass at the equator.

77.204
Figure 13-18.—Elementary Arma compass at the equator.

of the earth, straight down, as shown in A through E of figure 13-18. This pull of gravity has the same effect as a torque about the horizontal axis.

The mercury ballistic of the Sperry compass as shown in B of figure 13-16 applies a downward force on its SOUTH axle to cause precession to the west. Conversely, the weight W of the Arma compass has the same effect as a downward force on its NORTH axle to cause precession to the west. Because both types of compasses must precess in the same direction—that is, to the west—the rotors obviously must rotate in opposite directions to give this precession. The rotor of the Sperry compass rotates counterclockwise whereas the rotor of the Arma compass rotates clockwise when viewed from the south axle.

As the upward tilt increases, the torque, or pull of gravity, increases with the rate of precession to the west. When the gyroscope is on the meridian (E of fig. 13-16), the axis has reached the maximum in both tilt and the rate of precession. After the gyroscope has swung across the meridian, the tilt and the rate of precession diminish until the north end of the axle is at its farthest point west of the meridian and is again horizontal. At this point there is no precession because the weight is acting through the center of gravity of the rotor and therefore does not produce torque. However, the earth continues to rotate under the gyroscope. The north end of the axle drops below the horizontal, and, as the pendulous weight no longer hangs vertically down from the center of the rotor, a torque is again produced around the

C07 11710

169 OF 327

ED

056 238

MICROCOPY RESOLUTION TEST CHART

NATIONAL BUREAU OF STANDARDS-1963-A

horizontal axis. The precession resulting from this torque is toward the east. The downward tilt and the rate of precession increase until they are at a maximum value, when the axle is again on the meridian. As the axle crosses the meridian, the downward tilt decreases because the earth rotates under the gyroscope. The angle of tilt and the rate of precession decrease and become zero when the rotor is at its point of farthest travel to the east and is in the horizontal. Now the gyroscope axle is horizontal once more at the point where the oscillation first started. Oscillations continue as long as the gyroscope wheel continues to spin. As in the Sperry compass, the north axis of the Arma compass moves along an elliptical path.

Whatever the starting position may be, oscillations take place for both types of gyroscopes. The gyroscope precesses one way or the other until the axis is made level by the effect of the earth's rotation. The gyroscope then swings toward the meridian, crosses it, continues to the other side, becomes level again, swings back to the starting position, and continues the oscillations indefinitely.

PERIOD OF OSCILLATION

The time required for one complete cycle of this movement of the gyroscope wheel is called PERIOD OF OSCILLATION. The time is conveniently expressed in minutes. For a given wheel at a particular spot on the earth's surface the period is the same regardless of the angle through which the wheel oscillates.

The period of a north-seeking gyroscope is determined by the (1) size and shape of the rotor, (2) rotor speed, (3) torque developed by the mercury or liquid ballistic, or torquers (Sperry compasses), or the pendulous weight (Arma compasses), and (4) latitude. If a short period of oscillation is used, the gyrocompass is disturbed too greatly by ship motions such as speed and course changes, roll and pitch. Lengthening the period reduces the effect of these forces. Too long a period however, causes the compass to take an excessive amount of time to settle on the meridian after starting and after a disturbance.

Both Arma and the ballistic type Sperry gyrocompasses are built with an undamped period of 85 minutes at 40.7° north (New York) latitude. An undamped period of 85 minutes is long enough to prevent excessive disturbances of the compasses from the motions of the ship.

A graph representing the oscillations of a north-seeking gyroscope with a period of 85 minutes is shown in figure 13-19. Such a graph is known as an undamped curve. The original displacement of the gyroscope axle is 30° east of the meridian. In 21 1/4 minutes the axle reaches the meridian; after 42 1/2 minutes it is 30° west; at 63 3/4 minutes it is again on the meridian; and after 85 minutes it is back at its starting position, 30° east. The cycle is then repeated and continues indefinitely.

A gyrocompass with an undamped period of 85 minutes in one latitude has a different period in any other latitude. The nearer the gyrocompass is to the equator the shorter is the period; the farther away the gyrocompass is from the equator, the longer is the period. This is true because the tilt of the axle caused by the earth's rotation when the axle is not on a meridian is greatest at the equator. With zero tilt at the north pole there is no restraint to keep the gyrocompass axle from apparently turning about the vertical axis. Maximum tilt at the equator causes maximum restraint and maximum directive effort to cause the gyrocompass to precess toward the meridian.

To be useful as a compass, a north-seeking gyroscope must be made so that its axle settles in a position that is parallel to the meridian and to the surface of the earth, or nearly so. At any location except at the equator the north end of a level gyroscope normally is moved to the east or west by the effect of the earth's rotation. If a gyroscope is started with its axle level and pointed north in a north latitude, the rotation of the earth causes the north end of the axle to turn slowly toward the east and rise. Conversely, if a gyroscope is started with its axle level and pointed north in a south latitude, the rotation of the earth causes the north end of the axle to slowly turn toward the west and fall. It must, therefore, be made to precess to the west in a north latitude and to the east in a south latitude at the proper rate to cancel this effect of the earth's rotation. The rate of precession required is so slow that only a small angle of tilt is necessary in any latitude.

DAMPING THE OSCILLATIONS

The north-seeking gyroscope can never settle in the desired position as long as it oscillates across the meridian. Therefore, some means must be provided to suppress, or damp, the

94711

169

77.205

Figure 13-19.—Oscillation curve of an undamped compass.

oscillations by reducing the size of successive swings past the meridian until the swinging is stopped. When damped, the north-seeking gyroscope (1) settles with the tilt that is necessary to cancel the effect of the earth's rotation and (2) gives a continuous indication of true north. The time required for effective damping is about 4 hours for Arma and ballistic type Sperry compasses. The Sperry Mks 19 and 23 gyrocompasses are provided with fast settling systems which greatly reduce the time required for damping during starting.

Sperry Methods

Oscillations are damped in the Sperry gyrocompasses utilizing the mercury ballistic by employing a portion of the torque produced by the action of gravity upon the mercury ballistic to remove some of the tilt given the rotor axle by the rotation of the earth.

In the previously described mercury ballistic, the tanks are attached directly to the bearings at the ends of the shaft. In the actual compass the ballistic is pivoted on studs and bearings on an outside ring, called the PHANTOM RING, in such a way that its only point of contact with the gyroscopic element is through a connecting arm, or link, which bears against the bottom of the case in which the rotor spins (fig. 13-20). The rotor case corresponds to the inner ring of a gyroscope and holds the bearings on which the axle turns.

If the point of connection between the mercury ballistic and the rotor case is in the line of the vertical axis the only torque that can be exerted by the mercury ballistic is about the horizontal axis, and the resulting precession is only about the vertical axis. Thus, the compass would oscillate only back and forth across the meridian. However, if this point of connection between the ballistic and the rotor case is set a fraction of an inch to the east of the vertical axis (fig. 13-20), the force exerted by the mercury ballistic is applied about both the horizontal and the vertical axes, and torque is exerted about both the axes. Precession then results about both the vertical and the horizontal axes.

The Sperry Mk 22 gyrocompass utilizes a fraction of the weight of the followup pickoff armature to provide the torques for damping. Damping is accomplished for the Mks 19 and 23 gyrocompasses by the electronic control system mentioned previously.

Arma Method

In the Arma compass the oscillations are reduced by slowing down the rate of precession during each swing away from the meridian so that, in the time required for the axle to become level and start to swing back, the compass does not travel very far.

The damping arrangement used in the Arma compass consists of a fluid ballistic, as shown in figure 13-22. Two tanks, partly filled with a light oil, are secured to the rotor case in line with the north-south rotor axle on opposite sides of the rotor. The tube that connects the tanks has a small opening so that the oil flows slowly from one tank to the other. Unlike the action of the Sperry mercury ballistic the action of the Arma damping is delayed because of the small opening in the tube. The effect of this damping lags behind that of the pendulous weight.

If the north end of the gyroscope axle is elevated, the pendulous weight exerts a downward force on the high, or north, axle. At the same time oil begins to (1) flow from the north tank to the south tank and (2) exert a small force on the low, or south, end. Because of the small opening in the tube, the flow of oil is not effective for some time. If the tilt is maintained long enough, however, sufficient oil accumulates in the south tank to reduce the effect of the pendulous weight on the high end of the axle. The longer the tilt is maintained, the greater is the amount of oil in the south tank and the smaller is the net force exerted by the pendulous weight on the north axle.

If the tilt is reversed and the south axle is elevated, the excess oil in the south tank acts on the high end of the axle. The small opening in the tube prevents the oil from flowing immediately into the north tank. Hence, for a short time after the tilt is reversed the weight of the oil in the south tank adds to the force exerted by the weight on the high south axle.

In A of figure 13-23, the axle has just been tilted with the north end up, and the oil has not had sufficient time to run into the south tank in any great amount. In B of figure 13-23 the tilt has been maintained long enough for a large amount of oil to flow into the south tank, and the resultant force is greatly reduced. In C of figure 13-23 the tilt has just been reversed and there is still excess oil in the south tank. This excess oil adds to the pendulous weight and results in an increased force. In D of figure 13-23 the south axle has been tilted up for some time and the oil has built up in the north tank so that the effect of the weight has been reduced. The length of the arrows indicates the magnitude of the force that is being exerted.

Starting with the compass displaced 30° to the east of the meridian and level (point A, figure 13-24) the earth's rotations will cause the north axle to rise. This causes the pendulous weight to become elevated, the north axle up. This will produce a torque about the horizontal axis causing precession about the vertical axis to the west. However, due to the elevation of the north axle, it will cause the north tank to be elevated. This will cause a transfer of oil to the south tank. This transfer of oil to the south tank will be very slow because of the restriction in the connecting line and will not have much effect at the beginning.

As time goes on however, the oil accumulating in the south tank produces a torque about the horizontal axis opposing the torque produced by the pendulous weight making the net torque less than that produced by the pendulous weight

above. The rate of precession will be less because there is now less torque causing precession. The north axle of the compass will continue to rise as long as it remains east of the meridian so that the pendulous weight will always exert enough torque to cause it to reach the meridian (point B, figure 13-24). However, it cannot remain on the meridian because at this time it has maximum tilt, therefore maximum rate of precession. As the north axle of the compass crosses the meridian to the west, the earth's rotation will now cause the north axle to fall. This action further reduces the effect of the pendulous weight. As oil has been transferring to the south tank all this time because of the elevation of the north axle, a point is soon reached at which the torque produced by the oil ballistic is exactly equal and opposite to

77.210

Figure 13-24.—Path followed by the north axle of a damped Arma compass.

the torque produced by the pendulous weight. At this time the net torque about the horizontal axis is zero (point C, figure 13-24). Therefore precession to the west ceases. The north axle of the compass (being west of the meridian), continues to fall due to the earth's rotation however, further reducing the torque produced by the pendulous weight. The torque produced by the oil ballistic is now greater than that produced by the pendulous weight and causes precession to the east even though the axle has not yet become level. As the north axle becomes level (point D, fig. 13-24) there is still an excess of oil in the south tank due to the restriction in the oil line. This excess of oil in the south tank causes it to continue to precess to the east. The north axle continues to fall due to the rotation of the earth, however elevating the south axle. The pendulous weight now produces a torque about the horizontal axis that also causes precession to the east. At this time the oil ballistic and pendulous weight are exerting torques that are aiding each other. As the south axle is now elevated, however, oil will be transferring to the north tank until a point is reached where there is equal oil in both tanks (point E, figure 13-24). Precession continues to the east however, because of the torque produced by the pendulous weight. The south axle being elevated causes oil to continue to transfer to the north tank. This action produces an excess of oil in the north tank, causing a torque about the horizontal axis opposing that torque produced by the pendulous weight.

As long as the north axle remains west of the meridian, however, it will continue to fall, producing enough torque to cause it to reach the meridian (point F, figure 13-24). At this time,

11715

there is maximum tilt and maximum rate of precession, therefore, it cannot remain on the meridian. The north axle of the compass is now east of the meridian and will rise due to the earth's rotation further reducing the effect of the pendulous weight. As oil has been accumulating in the north tank during this time, a point is soon reached at which the torque produced by the oil ballistic is exactly equal and opposite to that produced by the pendulous weight. The net torque about the horizontal axis is now zero and precession to the east ceases (point G, figure 13-24). The north axle continues to rise due to the earth's rotation further reducing the effect of the pendulous weight. The oil ballistic is now producing a greater torque than the pendulous weight and causes precession to the west even though the north axle is not yet level. When the north axle becomes level (point H, figure 13-24), there is still an excess of oil in the north tank because of the restrictor in the connecting line which causes the compass to continue to precess to the west. As the north axle becomes elevated due to the earth's rotation, it raises the pendulous weight to the north which produces a torque about the horizontal axis that also causes precession to the west. The torques produced by the pendulous weight and the oil ballistic now aid each other. However, as the N-axle is now elevated, oil will transfer to the S-tank. A point is soon reached at which there is equal oil in both tanks (point I, figure 13-24). Precession continues to the west due to the pendulous weight. However, oil continues to transfer to the south tank which now produces a torque about the horizontal axis opposing the torque produced by the pendulous weight. The north axle will continue to rise as long as it remains east of the meridian. As it reaches the meridian it has maximum tilt and therefore maximum rate of precession and therefore cannot remain on the meridian (point J, figure 13-24). This action continues for about 2 1/2 oscillations at which time the compass has settled and is on the meridian.

Because of the restriction of the flow of oil, the effect of the damping tanks always lags behind the effect of the pendulous weight. This lag makes the oil ballistic useful as a damping device because the ballistic permits the weight of the oil to act at just the right time to oppose the oscillations away from the meridian.

The oscillation curve of an undamped compass compared to the oscillation curves of a damped Sperry and Arma compass are shown in figure 13-25. Note that the damped period for both compasses is somewhat larger than the undamped period and that the damped period of the Arma compass is larger than that of the Sperry.

The amount by which each successive swing past the meridian is reduced by the damping device is not the same for all swings. In the Arma compass it is less on the first swing than on the following swings. In the Sperry compass it is greater on the first swing than on succeeding swings. The average amount by which successive oscillations are reduced is called the percentage of damping or the damping factor. It is about 70 percent for Arma and ballistic type Sperry compasses.

The normal damping factor for Sperry Mks 19 and 23 compasses is 65 percent. This factor may be increased during starting as mentioned previously.

ERRORS

A gyrocompass installed aboard ship is subjected to many disturbing forces caused by the ship's linear speed, changes in course and speed, and roll and pitch. These forces, if not compensated for, would produce errors in the gyrocompass. Some errors are eliminated by the design of the compass, others are eliminated by calculating the amount of the error and correcting the compass either manually or automatically to the correct reading. Gyrocompass errors and the methods of correcting them differ depending upon the type and mark of gyrocompass concerned.

SPERRY MK 11 MOD 6 GYROCOMPASS

The Sperry Mk 11 Mod 6 gyrocompass is used principally on destroyers. The complete system consists of the master compass, the control system, alarm system, followup system, and the transmission system. The master compass includes five major components: (1) Sensitive element, (2) Mercury ballistic, (3) Phantom element, (4) Spider, and (5) Binnacle and gimbal rings. The binnacle and gimble rings enclose and support the other four major components (fig. 13-26).

11716

77.211

Figure 13-25.—Oscillation curves of undamped and damped compasses.

SENSITIVE ELEMENT

The sensitive element (fig. 13-27) is the north-seeking element of the master compass. It consists of the gyro unit, vertical ring, compensator weights, followup indicator, and suspension.

Gyro Unit

The gyro unit provides the directive force for the sensitive element that makes the compass north-seeking. The unit consists of the rotor and case (fig. 13-28). The gyro rotor (fig. 13-28B) is 10 inches in diameter, 4 1/2 inches wide, and weighs approximately 72 pounds. It is machined and balanced to rotate on special ball bearings at a normal speed of 11,000 rpm.

The gyro case (fig. 13-28A and C) includes a 3-phase, double-stator winding, one stator being mounted in each half of the case.

The case is made airtight and the rotor operates in a vacuum (26 to 30 inches of mercury) to reduce the friction caused by air resistance. A vacuum gage (not shown) is mounted near the top of the north half of the case to indicate the degree of vacuum.

A spirit level (gyro case level in fig. 13-27) is mounted on the lower part of the north side of the case to indicate the tilt of the rotor.

A small window (not shown) is provided in the south half of the case through which the spinning rotor can be observed during starting.

Vertical Ring

The vertical ring (fig. 13-27) is attached to a wire suspension from the head of the phantom element. The phantom ring is concentric with the vertical ring and surrounds the entire sensitive element. It is kept in alignment with the vertical ring, while the compass is in operation, by the action of the followup system, discussed later.

11717

40.35

Figure 13-26.—Sperry Mk 11 Mod 6 gyrocompass showing binnacle and gimbal rings.

An upper and a lower guide bearing prevent the vertical ring from moving laterally within the phantom ring.

The upper guide bearing has its outer race secured in the phantom ring. The inner race is formed by the lower stud of the suspension. The lower guide bearing has its outer race secured in the bottom of the vertical ring. The inner race is formed by a vertical stud that projects upward from the bottom of the phantom ring.

11718

40.30

Figure 13-27.—Sperry MK 11 Mod 6 sensitive element.

A gyro case lock (fig. 13-27) is provided to prevent the gyro case from tilting about its horizontal axis when the compass is not operating. This latch should be disengaged only when the rotor is running at normal speed. It is located on the lower part of the south side of the vertical ring.

A vertical ring lock (fig. 13-27) is provided to keep the vertical ring in line with the phantom ring when the compass is not operating. This lock prevents the wire suspension from acquiring a permanent set which would affect the settling point of the compass.

Compensator Weights

The compensator weights (fig. 13-27) are supported by two frames that are attached to the vertical ring. These frames project out beyond each end of the rotor axle. The weights are mounted concentrically on their studs, and their positions can be adjusted in the direction of the axis of the gyro rotor. The function of the weights is to provide an even distribution of the weight of the gyrocompass about the vertical axis.

The armature of the signal pickoff or followup transformer is attached to an arm that protrudes horizontally from the upper part of the south compensator-weight frame (fig. 13-27).

Followup Indicator

The followup indicator (not shown) indicates the position of the phantom element with relation to the sensitive element. This indicator consists of a scale and a pointer. The scale is attached to the phantom element below the

11719

40.31

Figure 13-28.—Sperry MK 11 Mod 6 gyro unit. B, rotor; A and C, case.

spider table and the pointer is attached to the north compensator weight frame. The scale is calibrated in degrees with the center marked "O". Thus, a misalignment between the phantom element and sensitive element is indicated in degrees.

Suspension

The suspension (fig. 13-27) suspends the entire sensitive element from the phantom element. It consists of a number of small steel wires secured at the upper end to a support stud and at the lower end to a guide stud. A nut and checknut secure the support stud to the phantom element, and provide a means to adjust the sensitive element vertically. The guide stud passes through a hole in the upper part of the vertical ring and is clamped to the ring by a nut. This stud also serves as the inner race of the upper guide bearing of the ring.

MERCURY BALLISTIC

The mercury ballistic (fig. 13-29) is that group of parts which applies the gravity controlling force to the gyro unit and makes it north-seeking. It consists of a rigid frame supported on bearings in the phantom ring. These bearings are in line with the horizontal case bearings in the vertical ring so that the mercury ballistic is free to tilt about the east-west axis of the sensitive element.

The frame supports a mercury reservoir in each of its four corners. The N and S reservoirs on the east side of the compass are connected by a U-shaped tube and the N and S reservoirs on the west side are similarly connected. The gravity controlling force of the mercury ballistic is applied to the bottom of the gyro case through an adjustable offset bearing stud mounted on the ballistic connection arm.

The connection bearing is offset to the east from the vertical axis by a short distance to provide the damping adjustment. When it is desired to eliminate damping, a solenoid (damping eliminator magnet) is energized by an automatic damping eliminator switch (discussed later) that attracts a plunger which moves the pivoted connection arm until the connection bearing is in line with the vertical axis of the gyro. In addition, each mercury reservoir is offset from its supporting stem so that each can be rotated around its stem through an arc of about 110° in order to vary the lever arm of

each tank. Thus the period of an undamped oscillation of the gyrocompass is maintained constant in all latitudes by adjustment of the mercury reservoirs. This adjustment is referred to as the ballistic latitude adjustment.

PHANTOM ELEMENT

The phantom element (fig. 13-30) is a group of parts that acts to support the sensitive element. It consists essentially of a hollow cylindrical stem that projects radially from the phantom ring, which is mounted in the spider and extends below the central hub of the spider table.

The phantom element supports the sensitive element by means of the suspension. The phantom element has no north-seeking properties of its own, however it does continuously indicate north, because it is made to follow all movements of the sensitive element by the action of the followup system.

A thrust bearing on the top of the stem (fig. 13-30) rests in the hub of the spider table and supports the weight of the phantom and sensitive elements. The upper and lower stem bearings keep the stem in alignment with the vertical axis of the spider but permit the phantom element to rotate about its own vertical axis.

The phantom ring also carries bearings that support the mercury ballistic. The axis of these bearings coincides with the axis of the horizontal bearings of the gyro case. Collector rings are mounted on the phantom stem below the upper stem bearing to connect the various electrical circuits from the fixed to the moving parts of the compass. The large and small azimuth gears are included in the azimuth followup mechanism (to be discussed later).

11721

40.33
Figure 13-30.—Sperry Mk 11 Mod 6 phantom element.

An eccentric groove called the cosine cam is cut into the upper surface of the large azimuth gear. The cosine cam is associated with the speed and latitude correction mechanism.

SPIDER

The spider (fig. 13-31) is a circular table of cast aluminum alloy that supports the entire inner, or moving, member of the compass by means of the hub on which the thrust bearing that supports the phantom element rests. The spider is supported in the inner, or cardan, ring of the two rings that comprise the gimbal system. A boss in the center of the table supports the thrust bearing and the upper and lower stem bearings.

The azimuth followup motor and the automatic damping eliminator switch are mounted on the forward side of the spider table. The speed and latitude correction mechanism and the auxiliary latitude corrector are mounted on the after side of the table. The 36-speed synchro transmitter is located on the port side and the single-speed synchro transmitter is located on the starboard side of the table.

CONTROL AND ALARM SYSTEM

The Sperry Mk 11 Mod 6 gyrocompass control and alarm system consists of a motor-generator, speed regulator, control panel, battery throwover panel, and bridge alarm indicator, with the necessary apparatus for the operation and control of the master compass. The principal components of the system are illustrated in figure 13-32.

The gyrocompass drive system consists of the primary and emergency sources of power. The primary power source is the ship's 3-phase, 120-volt, 60-cycle supply, and the emergency power source is the 24-volt battery supply.

Motor-Generator

Two separate motor-generator sets are provided with each complete Sperry gyrocompass equipment. Each set consists of an induction motor, a d-c emergency motor, an a-c generator, and a d-c generator (fig. 13-32). The induction motor and the d-c emergency motor are mounted on a common shaft in a single frame. The a-c generator and the d-c generator are also mounted on a common shaft in a single frame. The shafts of these two units are directly coupled together. Each motor-generator set is assembled as a complete unit and mounted on a single bedplate.

The INDUCTION MOTOR is a 3-phase, 120-volt, 60-cycle, wound-rotor motor with sliprings. Under normal operating conditions, the induction motor drives the d-c motor, the a-c generator, and the d-c generator. It operates at a constant speed of 1460 rpm (necessary for the a-c generator to deliver a constant 3-phase output of 55 volts at 195 cycles), which is maintained constant by means of a speed regulator that compensates for a maximum of ±10% variations in the ship's primary power supply frequency.

The d-c MOTOR is a shunt-wound machine. Under normal conditions of induction motor drive, the d-c motor operates as a self-excited d-c generator for charging the battery with

a continuous-duty rating of 27 volts at 7 amperes.

Under emergency operating conditions because of failure in the ship's 3-phase supply to the induction motor, the d-c motor operates from the battery supply to drive the a-c and d-c generators. As a d-c motor, it has an intermittent-duty rating of 22.5 volts at 70 amperes.

The a-c GENERATOR is a 3-phase, 60-volt, 195-cycle, inductor type generator having 16 polar projections. Both the field and the armature are stationary. The 16 polar projections (inductors) rotate continuously at approximately 1,460 rpm, thereby varying the magnetic field flux through the armature windings and generating a-c voltages at a frequency of 195 cps. The armature consists of a wye-connected, 3-phase winding, and the field consists of a single d-c winding. Sliprings are not required with this type of generator. The machine supplies power to drive the gyro rotor and to energize the amplifier and the followup system.

The d-c GENERATOR is a 120-volt, compound-wound, interpole, self-excited generator. This machine supplies excitation for its own

11723

40.36

Figure 13-32.—Sperry Mk 11 Mod 6 gyrocompass control and alarm system.

fields, the a-c generator field, and the azimuth-motor field. It also supplies d-c power for the damping eliminator, the azimuth-motor cutout relay, the dead reckoning equipment, and the voltage coil of the speed regulator.

Speed Regulator

The speed regulator (fig. 13-33) is a separate unit located adjacent to the motor-generator sets. It compensates for variations in the ship's supply voltage or frequency to maintain the speed of the induction motor constant and thereby causes the a-c generator to deliver a constant output to drive the gyro motor. The same speed regulator is used for each of the two motor-generator sets because they are not operated simultaneously.

The speed regulator consists of a wye-connected, carbon-pile voltage regulator connected in the form-wound rotor circuit of the 3-phase induction motor by means of sliprings.

The actuating coil of the speed regulator is connected in a shunt circuit across the output terminals of the d-c generator. It therefore responds to changes in d-c output voltage occasioned by any changes in speed of the motor generator. The voltage coil attracts a spring-loaded pressure arm that varies the pressure on the carbon piles in accordance with any change in voltage across the coil.

If the ship's supply voltage or frequency increases, the induction motor-rotor currents increase. This action causes a slight increase in the speed of the motor-generator. The consequent slight increase in d-c generator voltage causes the voltage coil of the speed regulator to attract the spring-loaded arm. This action decreases the pressure on the carbon piles. The accompanying increase in rotor-circuit resistance restores the rotor currents to their normal value and checks the rise in speed and d-c generator output voltage.

A dashpot damper is connected in the pressure arm to prevent hunting when rapid changes occur in the voltage or frequency.

Compass Control Panel

The compass control panel is located at the upper left-hand section of the gyrocompass switchboard (fig. 13-34). The control panel is

11724

40.38

Figure 13-33.—Speed regulator schematic.

used to control and indicate the operating conditions of the master compass. The ship's 3-phase, 120-volt, 60-cycle power supply and the ship's single-phase, 120-volt, 60-cycle power supply are connected directly to terminals on the back of the compass control panel. The 3-phase, 120-volt, 60-cycle power supply is fed from these terminals on the control panel through the battery throwover relay on the battery throwover panel to the motor-generator transfer switch on the compass control panel. The switches and fuses necessary for these power supplies are included on the IC switchboards, but are not provided on the gyrocompass switchboard.

The a-c ammeters and an a-c voltmeter are mounted at the top of the control panel to indicate the operating conditions of the master compass. One ammeter indicates the 60-cycle alternating current supplied to the synchro repeater system by the master compass transmitter, and the other ammeter and the voltmeter indicate the 195-cycle current and voltage respectively, supplied by the 3-phase, a-c generator to the gyrocompass rotor.

The azimuth-motor cutout detent release, the single and 36-speed overload signal lamps and the volt-ammeter selector switch are mounted just below the two ammeters and the voltmeter.

The azimuth motor cutout detent release is provided to reset the cutout after a fault has been cleared on the followup system.

The volt-ammeter selector switch is a 3-position rotary switch. The three switch positions provide for shifting the ammeter and voltmeter to any one of the three phases of

11725

40.39

Figure 13-34.—Sperry Mk 11 Mod 6 gyrocompass switchboard.

the a-c gyro rotor supply to obtain current and voltage readings of the selected phase.

The motor-generator transfer switch and the compass rotor switch are mounted on the third row from the top.

The motor-generator transfer switch is a double-throw rotary switch provided for selecting either one or the other of the two motor-generators.

The compass rotor switch connects the 3-phase, 55-volt, 195-cycle power from the a-c generator to the gyrocompass rotor.

The azimuth-motor switch, the alarm selector switch, the followup supply switch and the d-c service switch are located at the bottom of the control panel.

The azimuth-motor switch controls the (1) rectified a-c supply circuit to the azimuth

11726

motor armature and (2) the d-c supply to the azimuth-motor field.

The alarm selector switch is a rotary switch with four positions marked (1) normal, (2) low frequency, (3) repeater supply, and (4) ship's supply. In the NORMAL position, the alarm bell sounds if the ship's supply or the repeater supply fail or if the supply voltage or frequency fall below a predetermined value. The alarm bell is silenced by turning the selector switch to the position indicating the trouble.

The followup supply switch is an on-off switch. In the ON position it energizes the followup panel from one phase of the 3-phase gyro supply, and heats the filaments of the amplifiers and rectifier tubes in the followup system.

If the followup switch is in the OFF position, the compass supply ammeter and voltmeter indicate the current and voltage to the gyro rotor only; whereas, if this switch is in the ON position, the meters will indicate the 195-cycle current and voltage to both the gyro rotor and the followup panel.

The d-c service switch is the master switch for the 120-volt, d-c circuit. It supplies the (1) damping eliminator circuits, (2) azimuth-motor field, and (3) azimuth-motor cutout relay coil.

The fuses for the compass control panel are within an enclosure located at the bottom of this panel.

Battery Throwover Panel

The battery throwover panel is located directly below the compass control panel (fig. 13-34). It is used to transfer automatically the gyrocompass circuits from the ship's 3-phase supply to the battery supply in the event of failure of the ship's supply. The 24-volt storage battery is normally connected to the battery-charging generator of the motor-generator set and floats on the line.

If the ship's 3-phase supply voltage or frequency drops below the predetermined value (± 10% of the normal value), the movement of the pressure arm on the carbon piles of the speed regulator will open the battery throwover relay holding coil contacts, thereby deenergizing this relay. When this relay is deenergized, the (1) ship's 3-phase supply is disconnected from the motor-generator set, (2) battery is connected to the d-c motor (charging generator) as a primary power source so that the d-c motor becomes the prime mover for the motor-generator set, and (3) alarm bell rings.

When the ship's 3-phase power supply is restored, retransfer of the drive to the induction motor must be accomplished manually.

A 24-volt alarm supply switch and a battery voltmeter and ammeter are mounted at the top of the battery throwover panel.

The 24-volt alarm supply switch is a separate switch provided for cutting out the supply to the entire alarm system.

The d-c ammeter and the d-c voltmeter connected between the battery switch and the battery-generator transfer switch, indicate the current and voltage respectively in the battery line.

The fuses for the battery throwover panel are within an enclosure located in the center of the panel.

The battery switch and the battery-generator transfer switch are located on the left-hand and the right-hand sides of the fuse enclosure, respectively.

The battery switch is a DPST lever-switch that connects the 24-volt battery supply to the battery throwover panel.

The battery-generator transfer switch is a DPDT lever-switch that connects the battery to one or the other of the two battery generators.

The starting pushswitch is mounted below the battery switch. It is used to start the motor-generator and also to restore the circuit to the holding coil of the battery throwover relay after the system has been interrupted because of a failure of the ship's supply or low voltage and/or frequency.

An additional pushswitch in parallel with the starting pushswitch on the battery throwover panel is located on the bridge alarm indicator so that, if desired, the ship's power supply can be restored to the compass equipment from this station.

Two voltage adjustment rheostats, one for each of the battery charging generators, are mounted at the bottom of the panel. These rheostats are used to adjust the generator-field resistance to control the charging rate of the battery when the machine operates as a generator. The rheostats are cut out when the machine operates as a motor, and the resistance that is cut into the field by the battery throwover relay automatically increases the speed to the proper value.

11727

Bridge Alarm Indicator

The bridge alarm indicator (fig. 13-35) is located in the pilot house. The indicator includes a red, a blue, and a green indicator lamp, a damping-eliminator pushswitch and a starting pushswitch. These components are enclosed within a metal case provided for bulkhead mounting. An external alarm bell is located adjacent to this indicator.

The red indicator lamp in the battery supply indicates operation of the compass equipment from the 24-volt battery supply.

The blue indicator lamp is in the damping-eliminator circuit as a warning whenever the damping-eliminator coil is energized.

The green indicator lamp in the ship's a-c supply is lighted as long as the ship's supply is connected to the compass equipment.

Each indicator lamp is provided with a series variable resistor to control the intensity of illumination.

The starting pushswitch is in parallel with the pushswitch on the battery throwover panel as mentioned previously.

The damping-eliminator pushswitch is in parallel with the automatic damping-eliminator switch on the master compass and may be manually operated to energize the damping-eliminator coil and thus remove damping.

FOLLOWUP SYSTEM

The followup system includes the followup mechanism, the followup transformer, the azimuth motor, and the followup panel. The system functions to detect any misalignment between the phantom and sensitive elements and to drive the phantom element in the proper direction to restore alignment. Any misalignment between the phantom and sensitive elements results in a signal voltage output from the followup transformer. The amount of misalignment determines the magnitude of this signal voltage and the direction of misalignment determines its phase. The signal output from the followup transformer is amplified by a voltage amplifier and used to control the output of a power amplifier which operates the azimuth motor. The azimuth motor in driving the

77.212

Figure 13-35.—Bridge alarm indicator.

11728

phantom element back into alignment with the sensitive element also drives the single and 36-speed synchro transmitters, and a lost motion device through the azimuth followup gearing mechanism (fig. 13-36).

The azimuth motor is a d-c motor having its field excited from the 120-volt d-c output from the motor generator. Its armature is connected in either one or the other of the two output rectifier circuits of the power amplifier. The direction of rotation depends upon which pair of output rectifiers is conducting when the plates of the voltage amplifiers are positive.

Followup Panel

The followup panel (fig. 13-34) is located adjacent to the compass control panel. It includes a voltage amplifier and a power amplifier.

The voltage amplifier contains two twin triodes that amplify the weak signal voltage from the followup transformer. The power amplifier

40.40

Figure 13-36.—Azimuth followup mechanism gearing.

11729

contains two pairs of thyratron rectifiers that supply the azimuth motor armature current.

Followup Transformer

The followup transformer comprises three coils wound on an E-shaped laminated core (fig. 13-37). The primary coil (P) mounted on the center leg, is connected to the 3-phase, 195-cycle compass rotor supply. One primary lead is connected to one phase through resistor R1 which limits the primary current to a few ma. The other primary lead ties to the common connection of phasing resistors R2 and R3 across the other two phases. This provides the proper phase relation between the followup signal voltage and the followup amplifier bias and plate voltages.

An armature carried on the sensitive element serves as a closing link in the double magnetic circuit of the followup transformer. The armature is positioned so that a small air gap is maintained between the armature and the transformer.

Secondary coils A and B on the outside legs of the transformer are connected in such a manner that the induced voltage is one leg is 180° out of phase with the induced voltage in the other leg. Small capacitors C connected across the secondary coils, are in parallel resonance with the coils at 195 cycles in order to obtain the maximum voltage across the coils at that frequency. To balance the voltage of the secondary coils when the armature is centrally located, two fixed resistors (not shown) are connected across the capacitors.

77.213

Figure 13-37.—Simplified schematic diagram of followup transformer, Sperry Mk 11 Mod 6 gyrocompass.

The E-shaped followup transformer is mounted on the phantom element and will move with a change in the ship's heading. The armature, however, is mounted on the sensitive element or the north-seeking part of the compass and does not move once the compass has settled on the meridian.

With the compass settled on the meridian the phantom element is in alignment with the sensitive element, and the compass card will indicate the ship's heading. In this neutral position the voltages induced in the two secondaries of the followup transformer will be equal in amplitude, but differ in phase by 180 degrees. The output voltage, therefore, is zero and consequently no input signal is fed to the voltage amplifier.

However, when the followup transformer is moved either to the left or right, due to a change in the ship's heading, unequal fluxes pass through the transformer secondaries. As a result the secondary voltages become unbalanced. The resultant output voltage will be the vector sum of the two voltages and the phase of the output voltage will be the same as the phase of the secondary voltage having the greatest amplitude.

The phase of the output voltage is determined by the direction of the followup transformer movement and the voltage amplitude is determined by the amount of the movement.

Thus, the output signal from the followup transformer to the voltage amplifier is proportional in magnitude and phase to the amount and direction of the armature displacement or ship's movement.

TRANSMISSION SYSTEM

The Sperry Mk 11 Mod 6 gyrocompass transmission system provides a means of transmitting the readings of the master gyrocompass to a number of repeater compasses located at various stations in the ship. The single and 36-speed synchro transmitters (driven by the azimuth followup motor) control the movement of the repeater compasses that indicate the readings of the master compass at the remote stations.

The transmission system also includes the transmitter overload relays, repeater panel, relay transmitter repeater panel, relay transmitter, relay transmitter amplifier panel, differential alarm relay, and repeater compasses.

11730

Transmitter Overload Relays

Two similar transmitter overload relays, mounted on the back of the compass control panel, provide a visual alarm when an overload occurs in the transmitter circuits. One relay is connected in the single-speed transmitter circuit, and the other relay is connected in the 36-speed transmitter circuits. The relay consists of three legs with a coil on each leg. Each coil is connected in series with a transmitter stator lead. An increase in the current through any or all of the coils above a critical value attracts the relay armature, causing it to move. This action closes a contact that lights a red signal lamp on the panel front, indicating trouble in the transmitter circuit. A stepdown transformer (115 volts to 7 volts) on the panel supplies the indicator lamp circuits.

Repeater Panel

The repeater panel (fig. 13-34) is located below the followup panel. It comprises an assembly of rotary switches, and auxiliary equipment. Each switch with its associated fuses and overload indicating devices is assembled as a unit and can be withdrawn from the front of the panel for inspection and repair.

Each compass repeater switch is arranged to connect the circuits of two repeater compasses so that either one, or both, may be driven by the master compass transmitters.

Each repeater circuit is provided with an overload indicator, comprising a transformer and a neon lamp. The transformer has two primaries, which are connected in series respectively with two of the three secondary leads to the repeater. The transformer secondary is connected across the neon lamp. When the repeater is approximately alined with the transmitter, the very small current in the transformer primaries does not generate sufficient voltage across the secondary to illuminate the lamp. However, excessive current in the transformer primaries causes the lamp to glow and thus indicate trouble in this repeater circuit.

Associated with each of the repeater circuit switches are four fuses, access to which is through the hinged door just above the switch handle. Two of the fuses are in the primary circuit to the 1-speed repeater, and the remaining two are in the primary circuit to the 36-speed repeater.

The rotary type switch designated on the panel as the fire control switch is not provided with an overload alarm because connections are made from this switch to the fire control switchboard, which has an alarm for each circuit leaving the board. However, at the fire control switch on the repeater panel the two indicators are (1) a pilot lamp, connected across the a-c supply to this switch and therefore illuminated as long as this supply is available, and (2) a transformer and neon lamp arranged to indicate when one or both of the a-c supply fuses blow.

The rotary type switch designated on the panel as the dead reckoning analyzer switch is provided to operate the DRA from the underwater log transmitter and the 1-speed transmitter on the master compass. This switch also supplies single-phase, 120-volt, a-c power and 120-volt, d-c power necessary for the operation of the DRA. Each of these circuits is provided with two fuses. A neon lamp across each fuse in the d-c circuit is lighted when a fuse blows.

Relay Transmitter Repeater Panel

The relay transmitter repeater panel (fig. 13-34) is located adjacent to the repeater panel. This panel and the repeater panel are arranged so that the repeater compasses can be connected to either the master-compass transmitter or to the relay transmitter.

The relay transmitter repeater panel includes eight rotary switches. These include a checking repeater switch, a fire control switch, a relay transmitter supply switch, an emergency navigation transfer switch, two compass repeater switches, and two radar mast (special) switches.

The checking repeater switch connects the gyrocompass room checking repeater to either the master compass or to the relay transmitter. Two fuses are connected in series with the primary leads on the load side of the switch. Two transformer and neon-lamp overload indicators (one for each circuit) are connected in the transmitter secondary circuits to indicate an overload in these circuits.

Relay Transmitter

In order to actuate a number of repeater compasses without imposing this load directly on the compass transmitters, an intermediate instrument known as a relay transmitter is used. The relay transmitter (fig. 13-38) consists

of a single-speed and a 36-speed synchro control transformer (CT), a commutator transmitter, a followup motor, and a reactor. These components are enclosed within a metal case provided for bulkhead mounting (fig. 13-38A).

The relay transmitter is synchronized with the master compass by means of the synchro control transformer followup motor, and relay-transmitter amplifier (fig. 13-38B). The controlling signal voltage from the master compass energizes the primaries of the control transformers. The output of the control transformers is fed to the amplifier, the output of which controls the followup motor. The followup motor drives a commutator type transmitter, the output of which energizes the repeaters, causing them to follow the master compass. The followup motor also drives the secondaries of the control transformers to the zero-voltage position, thereby synchronizing the relay transmitter with the master compass.

Relay Transmitter Amplifier Panel

The relay transmitter amplifier panel (fig. 13-34) is located adjacent to the followup panel. It consists of a voltage amplifier and a power amplifier. The voltage amplifier receives the signal from the control transformers, and the output is fed to the power amplifier. The power amplifier provides the controlled power necessary to operate the followup motor in response to the signals from the voltage amplifier.

Differential Alarm Relay

The differential alarm relay (fig. 13-39) is a device for sounding an alarm whenever the relay transmitter loses synchronism with the master compass. The amount by which the transmitter is allowed to diverge, before the alarm is sounded, is adjustable from 0° to 2.5°.

The device comprises a synchro differential receiver. The stator receives its signal from the 36-speed output of the relay transmitter; the rotor circuit receives its signal from the 36-speed transmitter at the master compass. As long as the two outputs are in agreement, the rotor remains at the neutral position. Failure of the relay transmitter to keep in synchronism causes the rotor to move from the neutral position to that amount corresponding to the divergence from synchronism.

A bakelite disk that has a metallic segment is mounted on the shaft of the differential receiver (fig. 13-39A). Two trolleys are arranged so that rotation of the disk causes one trolley to contact the metallic segment. This action closes the 120-volt, a-c circuit to a relay (fig. 13-39B), which in turn, closes the 120-volt, a-c supply to the alarm bells located in the pilot house.

An 8-pole switch on the relay transmitter repeater panel is provided for disconnecting the differential synchro receiver and the alarm circuit (fig. 13-39B). The toggle switch disconnects only the alarm circuit.

AUTOMATIC CORRECTION DEVICES

The Sperry Mk 11 Mod 6 gyrocompass is provided with two automatic devices associated with error correction. They are (1) an automatic speed corrector associated with speed course, latitude error correction, and (2) an automatic damping eliminator which prevents the introduction of ballistic damping errors during rapid changes in ship's speed or course.

Automatic Speed Corrector

The SPERRY AUTOMATIC SPEED CORRECTOR (fig. 13-40) automatically transmits corrections for the ship's speed to the speed correction mechanism on the master compass. The step-by-step motor geared to the corrector spindle on the speed correction mechanism (fig. 13-41) is remotely controlled by a step-by-step transmitter in the automatic speed corrector. A switch is mounted on the compass for opening the motor circuit when setting the correction device by hand.

The automatic speed corrector is contained in a metal box, mounted on the bulkhead in the vicinity of the master compass.

The ship's speed is introduced into the automatic speed corrector by a synchro motor controlled by the underwater log. In operation, the rotor of the synchro motor takes a position representing the ship's speed and correspondingly locates a pair of trolleys bearing on a followup ring assembly (fig. 13-42).

When the position of the trolleys is not on the gap in the followup contact rings, the followup motor is energized. The motor drives a three-dimensioned cam, which, by means of a follower and gears, drives the followup contact rings into synchronism with the trolleys. The cam is

11734

40.48

Figure 13-40.—Sperry automatic speed corrector.

designed so that when it is correctly positioned lengthwise for the local latitude, the amount it must turn to synchronize the trolleys and rings is proportional to the speed correction that must be set into the compass. This correction is transmitted to the step-by-step motor on the compass by a step-by-step transmitter driven by the followup motor that rotates the cam. The followup motor also drives a centrifugal type damping-eliminator switch to eliminate damping during rapid changes in speed.

The instrument (fig. 13-40) is provided with a dial to indicate the ship's speed, graduated in knots, and visible through a window in the cover. The latitude adjustment, which determines the lengthwise position of the three-dimensioned cam, is shown on another dial, also visible through a window in the cover.

Automatic Damping Eliminator

The automatic damping eliminator used with the Sperry Mk 11 Mod 6 (fig. 13-43) consists of two centrifugal switches, one geared to the azimuth motor, and one to followup motor of the automatic speed corrector; and an electromagnet that moves the mercury ballistic connecting arm from its offset position to a true vertical position.

The switch geared to the azimuth motor takes care of changes in course where no change in speed is involved. This switch consists of a flyball governor driven through a gear train which speeds the governor shaft to about 4300 revolutions to one revolution of the phantom. To eliminate constant starting and stopping of the governor when the ship is yawing, a lost-motion mechanism and a helical driving spring are inserted between the switch driving gear in the azimuth motor train and the first gear in the train to the governor shaft. As the ship yaws, the lost-motion mechanism comes into play. This mechanism prevents transmission of motion to the governor shaft.

If the ship turns more than 15 degrees, the helical spring is wound in one direction or the other until there is sufficient tension in the spring to set the governor in motion. As the governor spins, the balls fly up, raising a sliding collar on the governor shaft which engages an arm operating the magnet circuit contact, thus closing the 115-volt, d-c supply circuit to the damping eliminator magnet.

A friction brake on the governor, and a spring disk friction clutch in the gear train, prevent the governor from spinning too fast. The contacts are adjusted so that the circuit is closed when the ship turns at a rate of more than 40 degrees per minute.

The gearing arrangement from the azimuth motor through the lost motion device to the flyball governor is also shown in figure 13-36.

The damping-eliminator switch (fig. 13-42) driven by the followup motor in the automatic speed corrector operates in a similar manner to eliminate damping during rapid changes in ship's speed.

OPERATION

Operating the compass consists of starting, stopping, adjusting correction devices, and making checks for any indications of abnormal operation conditions.

Starting the Compass

If possible the compass should be started at least four hours before it is needed for service. Before starting make sure that all switches on the compass and repeater switchboards are off. Ensure that the gyro case lock and vertical ring lock (fig. 13-27) are in the locked position, and that the vacuum gage (not shown) indicates

11735

40.49

Figure 13-41.—Speed correction mechanism.

approximately 28 inches. Take hold of both sides of the phantom and vertical rings and turn slowly until the compass card indicates the approximate heading of the ship. Never turn the compass by exerting pressure on the compensating weights or mercury ballistic. Check the oil sight glass to ensure that the rotor bearings will be supplied with oil. Set the auxiliary latitude corrector, and the ballistic latitude adjustment to the proper settings (discussed later). After completing the above checks, proceed to start the compass as follows:

1. After closing the necessary supply switches on the IC switchboard, turn the MOTOR-GENERATOR TRANSFER switch on the control panel (fig. 13-34) to the motor-generator set desired.

2. Press the STARTING PUSH-BUTTON, turn the COMPASS ROTOR switch to the motor-generator set in use, then close the D-C SERVICE switch.

3. When the gyro rotor has been running for about 30 minutes, close the followup supply switch, then wait approximately 15 minutes for the gyro rotor to come up to normal speed. Normal speed will be indicated by a reading of approximately 60 volts of the COMPASS ROTOR SUPPLY VOLTMETER (fig. 13-34), and from 2 to 3 amperes on the COMPASS ROTOR SUPPLY AMMETER when the VOLTAMMETER SELECTOR switch is in the number 1 phase position.

4. Release the VERTICAL RING LOCK (fig. 13-27), then release the GYRO CASE LOCK. Be sure to release the VERTICAL RING LOCK first.

5. Turn the AZIMUTH MOTOR SUPPLY switch on the control panel (fig. 13-34) to ON, and note whether the azimuth motor starts operating. It may be necessary to press the AZIMUTH MOTOR CUTOUT DETENT RELEASE (fig. 13-34) to complete the circuit to the azimuth motor.

6. Turn the BATTERY GENERATOR TRANSFER switch on the battery throwover panel to the motor-generator set in use, close

11736

40.50

Figure 13-42.—Schematic diagram of Sperry automatic speed corrector.

40.51

Figure 13-43.—Schematic diagram of Sperry automatic damping eliminator.

the BATTERY switch, and adjust the battery charging rate with the VOLTAGE ADJUSTING RHEOSTAT.

7. Level the rotor case, then precess the compass to the approximate heading of the ship. To level the rotor case, apply a slight pressure on one side of a rotor case bearing housing as if to turn the compass in azimuth. If the rotor case starts to tilt in the wrong direction, apply the pressure to the other side of the housing. To precess the compass in azimuth, apply a slight downward pressure from the top of a rotor case bearing housing. If the compass starts to precess in the wrong direction, apply the pressure upward from the bottom of the housing.

8. Close the repeater supply switch on the IC switchboard (not shown), the 24 VOLT ALARM switch on the battery throwover panel (fig. 13-34), and the rotary switches for the relay transmitter supply and differential alarm relay on the relay transmitter repeater panel (not shown).

9. Close the switch on the relay transmitter (fig. 13-38).

10. Close the FOLLOWUP switch on the relay transmitter amplifier panel (fig. 13-34), wait about one minute for the tube filaments to heat up, then close the AZIMUTH MOTOR switch. The relay transmitter should synchronize immediately to the same heading as the master compass.

11. Close the toggle switch on the differential alarm relay (fig. 13-39), and turn on all repeaters.

Setting Correction Devices

The gyrocompass operator must ensure that all error correction devices are properly set before starting the gyrocompass. While the ship is underway, he is further concerned with adjusting these devices. For the Sperry Mk 11 Mod 6 gyrocompass system, these devices include the Speed and Latitude Corrector, the Automatic Speed Corrector, the Auxiliary Latitude Corrector, and the Ballistic Latitude Adjustment.

SPEED AND LATITUDE CORRECTOR.—To set the speed and latitude corrector (fig. 13-41) without utilizing the automatic speed corrector, turn the knurled knob at the upper center of the corrector until the point on the latitude scale corresponding to the local latitude intersects the speed curve corresponding to the ship's speed. For maximum accuracy the corrector should be kept within 2 degrees of the local latitude and within 2 knots of the ship's speed. It is impractical, however, to attempt to keep the speed settings within these limits without utilizing the automatic speed corrector.

11737

To put the automatic speed corrector in operation, set the speed and latitude corrector (fig. 13-41) at zero, and turn the corrector step-by-step motor switch to ON. After the ship is underway and the underwater log is in operation, turn the switch on the upper right side of the automatic speed corrector (fig. 13-40), to ON. Set the corrector (fig. 13-40) to the local latitude with the latitude adjusting knob. Adjust the latitude setting when the ship's latitude changes as much as two degrees or as ordered by the ship's navigator.

AUXILIARY LATITUDE CORRECTOR.—To set the auxiliary latitude corrector, turn the smaller knurled knob on the right side of the corrector (fig. 13-41) until the line engraved on the large gear segment coincides with the point on the latitude scale corresponding to the local latitude. Change this adjustment for changes in ship's latitude of 2 degrees, or as ordered by the ship's navigator.

BALLISTIC LATITUDE ADJUSTMENT.—To make the ballistic latitude adjustment, turn the knurled latitude setting thumbwheel (fig. 13-29) until the pointer on the ballistic frame points to the local latitude on the latitude scale located on top of the mercury reservoir. Make the same adjustment on the opposite side of the ballistic. Make these adjustments for changes in latitude of 10 degrees, or as ordered by the ship's navigator.

Stopping the Compass

To stop the Sperry Mk 11 Mod 6 gyrocompass, proceed as follows:

1. Turn the switch on the automatic speed corrector, and the step-by-step speed corrector motor switch on the master compass to OFF.
2. On the battery throwover panel (fig. 13-34) open the 24-volt alarm switch, the BATTERY switch, and the BATTERY GENERATOR TRANSFER switch.
3. Open the toggle switch on the differential alarm unit, then open the AZIMUTH MOTOR switch and the FOLLOWUP switch on the relay transmitter amplifier panel.
4. Open all repeater switches, and the rotary switch for the differential alarm unit.
5. Open the AZIMUTH MOTOR SUPPLY switch on the control panel, then lock the GYRO CASE, and VERTICAL RING LOCKS (fig. 13-27). Be sure to lock the gyro case lock first.
6. On the control panel (fig. 13-34) open the FOLLOWUP SUPPLY switch, the D-C SERVICE switch, the COMPASS ROTOR switch, and the MOTOR GENERATOR TRANSFER switch.
7. Open the repeater supply, and control panel supply switches on the IC switchboard, (not shown).

Indications of Normal Operations

Normal operating conditions for the compass system are indicated by the various electrical meters and overload indicators on the gyrocompass switchboard (fig. 13-34). Normal readings for the electrical meters are listed in the manufacturer's technical manual, NavShips 324-0020. As these readings may vary slightly for different installations, the average meter readings during actual normal operation should be recorded and used as the normal readings.

Normal operating conditions are also indicated by the gyro case level and vacuum gauge on the sensitive element, and the presence of the blue frame in the compass followup and relay transmitter power amplifier thyratrons.

Study the gyrocompass installation on your ship and become familiar with all indications of normal operation. This will enable you to recognize any abnormal condition immediately.

You may be assigned to a ship with a large complement of IC electricians and therefore not be required to concern yourself with the gyro watches. You should bear in mind however, that your next duty station may be on a small ship that has no IC electrician onboard, and you as an EM 3 or 2 may be the one required to carry out the duties of the gyro watch.

Regardless of the type of ship to which you are assigned ask your division PO to assign you some familarization watches with the IC gang or use your off duty time if necessary to learn the proper procedures for starting, adjusting and securing the gyrocompass.

11738

CHAPTER 14

ELECTRIC PROPULSION

Electric propulsion installations use rotating electrical machinery for the transmission of power from the prime movers to the ship's propeller(s). Electric generators driven by the propulsion prime movers supply electric power to the propulsion motors, which are connected to the propeller shafting, either directly or through reduction gear units. The electric power generated is either a-c or d-c power and the installation is classified accordingly as an a-c or d-c system.

Steam turbines and diesel engines are used as prime movers in electric drive installations on naval vessels. Turbines are generally used only with a-c generators because turbine speeds are high for d-c generators. Diesel engines can be used with either a-c or d-c generators, but almost all diesel electric installations in naval vessels use d-c generators.

In the era of transition between the slow-speed steam reciprocating engine and high-speed steam turbines for ship propulsion, large reduction gears had not been sufficiently developed to provide reliable service on naval capital ships. Electric propulsion, on the other hand, had successfully proved itself on the first electrically propelled naval surface ship, the collier Jupiter, which was later converted to the aircraft carrier Langley. The favorable service record of this vessel strongly influenced the application of a-c turboelectric propulsion on two aircraft carriers and seven battleships completed shortly after World War I.

Soon after the completion of these vessels, turbine-geared drive came into extensive use on merchant and passenger vessels and proved itself highly successful. While electric drive permitted greater flexibility in arrangement of machinery and proved more economical at cruising speeds, the greater savings of weight and space with reduction gears outweighed these advantages in large surface ships. Thus, when construction of capital ships was resumed after 1930, the use of reduction gears for propulsion plants in the higher ranges of power capacity had been standardized by the Navy, and no further installations of electric propulsion were made on capital ships.

This standardization of turbine reduction-gear drive for large combatant ships did not, however, eliminate electric propulsion from consideration on vessels requiring propulsion of medium or small capacities. The Navy has continued to install electric propulsion on certain types of surface vessels for the following reasons:

1. Direct-current electric propulsion provides exceptional operating flexibility at reduced speeds and under towing conditions; thus it is highly desirable for tugs, icebreakers, salvage ships, net-laying ships, and survey ships.

2. Propulsion generators of an electrically propelled vessel may be used to provide power for large pumps, cargo-handling gear, and other purposes. They have been used to advantage on tugs equipped with large motor-driven fire pumps, tankers equipped with large cargo pumps, and mine sweepers with magnetic sweeps. Submarine tenders such as the AS-31 and 32 provide a-c power to nuclear powered submarines while alongside by means of the tender's propulsion generators.

3. In World War II, the availability of reduction gears for propulsion became critical. Because electric propulsion could serve the same purpose of reducing speeds between the propulsion engines and the propeller shafts and could be procured more readily than reduction gears, it was widely used on several classes of vessels, particularly on escort vessels (DE).

4. Electric propulsion permits maximum flexibility in the number, size, speed, and type of prime movers. This feature was of special importance during World War II when the choice of diesel engines was limited to those most readily available. Electric propulsion not only provided the necessary speed reduction but

OPTI-

11739

permitted shipboard machinery arrangements best adapted to the types of vessels involved.

There are three types of electric drive in use aboard naval vessels today: diesel d-c drive, diesel a-c drive, and turbine a-c drive. Adaptability of these types to various horsepower requirements and their applications to naval surface vessels is discussed below.

1. Diesel d-c drive is suited to vessels in the horsepower range from 300 up to 21,000 shaft horsepower. It has been installed in approximately 175 escort vessels and 500 surface vessels of other types, including mine sweepers, icebreakers (the AGB-4 has two 10,500-hp d-c motors), 11,500-hp submarine tenders, fleet and harbor tugs, fuel-oil tankers and barges, rescue and salvage vessels, net-laying ships, freighters, coast guard vessels, ferries, and miscellaneous unclassified vessels.

2. Diesel a-c drive is best adapted to medium horsepower installations ranging from about 4000 to 15,000 shaft horsepower. Its application so far has been limited to submarine tenders AS12, AS31, and AS32.

3. Turbine a-c drive is best suited to installations of about 6000 shaft horsepower or more. Approximately 350 naval vessels have been equipped with a-c turbine electric drive. These include escort vessels (DE), cargo and troop transports (AP, APD, APA, AKA), and oilers (AO).

This chapter will discuss the turbine electric a-c propulsion system used on DE-51 class escort ships, and the diesel electric d-c system used on fleet tugs. A number of APDs (high speed transports), have the same propulsion system as the DE-51 class.

TURBINE ELECTRIC A-C PROPULSION

The arrangement of a turbine electric a-c propulsion installation in U.S. DE51 class escort vessels is illustrated by the block diagram in figure 14-1. The installation consists of two turbine-driven propulsion generators, which furnish power through two individual control cubicles to two propulsion motors, which in turn, drive the propellers. Each generator normally supplies power to one of the propulsion motors. The motors are directly connected to their respective propeller shafts. The turbine generators always rotate in the same direction. Reversal of the motors is accomplished by

77.226

Figure 14-1.—Turbine electric a-c propulsion installation in destroyer escort.

11740

interchanging two of the phase connections to the motors. Speed control is accomplished by control of the turbine speed.

Two similar propulsion control panels are provided, one for the forward engine room and one for the after engine room. Operation of the equipment is by means of levers mounted in the control panel.

In addition, two ship's service turbine-generator sets and associated switchboards are provided, one in the forward engine room and one in the after engine room. These generators supply the ship's lighting and power requirements and the power for the propulsion exciter motor-generator sets through the vital propulsion auxiliary panel (fig. 14-2).

PROPULSION GENERATORS

The two propulsion generators are 3-phase, 3-wire, 2-pole, separately excited, self-ventilated machines. Each generator is directly coupled to a steam turbine through a solid coupling forged to the shaft. Ventilation is provided by a fan mounted on each end of the rotor shaft. The air is recirculated through a single section cooler located on top of the generator frame. Electric heaters are mounted in the generator under the end windings to prevent condensation in the windings when the generator is secured.

Each propulsion generator is rated at 4600 kva, 2700 volts, 93.3 cycles, 1.0 power factor, and 5600 rpm. At reduced turbine speed the generator frequency and voltage are reduced proportionately.

PROPULSION MOTORS

The two propulsion motors are 3-phase, 3-wire, 28-pole separately excited, self-ventilated synchronous motors. Each motor is flanged-coupled to a propeller shaft. A fan mounted on each end of the rotor forces air through the motor and recirculates it through a cooler located on top of the stator frame. To prevent the accumulation of moisture in the windings during periods of inoperation, electric heaters are mounted in the lower part of the motor frame.

Each propulsion motor is rated at 6,000 horsepower, 2,700 volts, 984 amperes, 93.3 cycles, 1.0 power factors, and 400 rpm. The motor speed is 2/28, or 1/14, of the generator speed. Thus, the motor operates at its synchronous speed of 400 rpm at the rated generator speed of 5600 rpm. A squirrel cage winding is provided for use when the motor is operated as an induction motor during starting periods.

PROPULSION EXCITERS

The two propulsion exciter motor-generator sets are identical. Each set consists of an 85-hp 440-volt, 3-phase, 60-cycle motor and a 60-kw, 110-volt, d-c exciter mounted on the same shaft. A 3-kw, 125-volt, amplidyne generator is mounted above the main exciter and is belt-driven from its shaft, the main exciter provides the field current for both the propulsion motor and generator.

The main exciter field is energized from the amplidyne generator on regulator control and from the 120-volt, d-c vital bus on manual control.

Under automatic control, the voltage regulator is connected to the three amplidyne generator fields, which govern the amplidyne generator armature current, and thus control the exciter field current. During synchronous operation the regulator holds the voltage proportional to the speed.

PROPULSION CONTROL PANELS

The two propulsion control panels are similar. Each panel (fig. 14-3) consists of the various instruments, handwheels, operating levers, and protective devices necessary for the operation of the propulsion equipment. A brief description of the operation of each unit shown in figure 14-3 follows.

1. Phase Balance Relays.—Protect the main propulsion generator and motor against phase faults resulting from a short circuit between phases or to ground or from an open circuit in one phase. The relays compare the current in each of the three phases and operate if there is 25 percent or more unbalance between phases. Closing of the relay contacts energizes the trip coil of the motor and generator field contactors, causing them to open.

2. Ground Protective Relay.—Protects the generator in case of a ground. It has a single operating coil which is connected to a current transformer in the generator neutral line to ground. Should one of the generator phases become grounded, current will flow in the neutral line energizing the operating coil of the ground protective relay, causing the relay to close its contacts and completing the trip circuit for the motor and generator field contactors.

11743

3. Nameplate for Generator Field Amp.—Shows the maximum safe generator field amps for a given rpm during periods of manual control.

4. Excitation Set Starting Switch.—A manually operated start-stop switch for starting and stopping the 60-kw exciter motor generator set. The STOP position is ineffective unless the reverser lever is in the OFF position.

5. Test Block.—Provided for testing or calibrating the meters.

6. Standby Exciter Control Switch.—Provided for selection of manual or automatic control of the excitation voltage for the 60-kw exciter field.

7. Engineroom Telegraph.—Provided for receiving and acknowledging engine orders for standard speed changes.

8. Clock.—Provided to indicate time at which orders are received for recording in the log.

9. Generator Field Ammeter.—Indicates the generator field current. It has a 0-300 ampere scale and is red-lined at 122 amperes.

10. Turbine Speed Indicator.—Indicates the rpm of the generator turbine. It has a 0-6000-rpm scale and is actuated by a small tachometer generator attached to the turbine shaft.

11. Generator Indicating Wattmeter.—Indicates the kw output of the main propulsion generator. It has a 0-7000-kw scale.

12. Motor Field Ammeter.—Indicates the motor field current. It has a 0-300 ampere scale and is red-lined at 200 amperes.

13. Exciter and Ground Detector Voltmeter.—Provided to indicate the voltage output of the 60-kw exciter and for use as a ground detector to check for grounds on the various control circuits. It has a 0-300 volt scale.

14. Generator Ammeter.—Indicates the generator line current. It has a 0-2000 ampere scale and is red-lined at 984 amperes.

15. Generator Voltmeter.—Indicates the voltage output of the main propulsion generator. It has a 0-3500 volt scale and is red-lined at 2700 volts.

16. Stator Coil Temperature Indicator.—Is used in conjunction with test switches 22 and 23 to indicate the temperature of the main motor and main generator stators.

17. Indicating Lamp Control Bus.—Green lamp glows when the control bus is energized.

18. Indicating Lamp Wrong Direction Indicator.—Red lamp glows when the reverser lever is operated in the wrong direction in response to an engine order signal from the bridge.

19. Indicating Lamp Heater.—Red lamp glows when the main motor and generator heater are energized.

20. Exciter Voltmeter and Ground Detector Switch.—Is provided for selecting the circuit voltage to be read on voltmeter 13.

21. Control Switch.—Energizes the control bus from the 120-volt d-c vital bus.

22. Motor Stator Temperature Indicator Switch.—Provided to select the phase in the motor stator whose temperature is to be used.

23. Generator Stator Temperature Indicator Switch.—Provided to select the phase in the generator stator whose temperature is to be read.

24. Shaft RPM Indicator and Revolution Indicator.—Is provided to indicate the instantaneous rpm of the port shaft and to count the total rpm the shaft has turned.

25. Shaft RPM Indicator and Revolution Indicator.—Has the same function as 24 for the starboard shaft.

26. RPM Telegraph.—Is provided for receiving and acknowledging engine orders for small changes in speed.

27. Load Limit Control Release.—Is provided to release the load limit control handwheel.

28. Load Limit Control Handwheel.—Is provided to limit the maximum steam flow to the turbine at low speeds.

29. Exciter Field Rheostat.—Is provided for manual control of the exciter field voltage.

30. Motor Setup Lever.—Is provided to connect the two main motors in parallel for two-motor operation or connect them separately for single-motor operation.

31. Field Lever.—Is provided to energize the main motor and generator fields.

32. Reverser Lever.—Is provided for connecting the phases of the main motor for ahead or astern rotation.

33. Governor Control Lever.—Is provided for controlling the main generator turbine speed and thus controlling the main motor speed.

34. Emergency Lever.—Is provided for controlling the generator turbine speed in the event of a casualty to the governor control lever 33.

35. Turbine Trip Handle.—Is provided for tripping the turbine steam throttle valves closed in an emergency that requires stopping the turbine.

11744

11744

Operating Levers

The operating levers comprise the motor setup lever 30, field lever 31, reverser lever 32, turbine governor lever 33, and emergency control lever 34. These levers are interlocked mechanically and electrically to prevent improper operation of the equipment. Figure 14-4 summarizes this interlocking.

OPERATION

In order to follow the schematic diagram of control circuits that appear later in this chapter and to fully understand the operation of the system, one must realize the need for regulating the voltage output of the main propulsion generator at varying propeller speeds. The need for this voltage regulation, and how the 3GNA8A voltage regulator operates to satisfy this need, is discussed below.

In contrast with the usual alternating current power systems in which the voltage and frequency are maintained constant, the turbine electric propulsion system operates with variable voltage and frequency. The propulsion synchronous motors start as induction motors on reduced voltage and accelerate to a speed equal to synchronous speed minus the slip. Direct current is then applied to the motor fields, pulling the motor into synchronism with the generator. Thereafter propeller speed is controlled by changing the speed of the turbine which in turn changes the frequency and voltage output of the generator. For desirable operating characteristics the main propulsion generator voltage must be maintained, as near as posssible, at constant volts per cycle; that is, the generator voltage must be maintained at such a value that the voltage divided by the frequency is constant. Recalling the voltage generated per phase in alternating current generators, one might surmise that constant volts per cycle would be maintained by the main propulsion generator without adjustment of generator field strength. However, such is not the case with varying loads.

The propulsion motors must supply sufficient torque to start and accelerate the shaft, to turn the shaft for steady running conditions, and to turn the shaft when reversing or maneuvering. The "break away" torque required to overcome friction and start the shaft varies from 5 to 15 percent of full-load torque. However, after the propeller starts to rotate, the torque required to overcome friction decreases rapidly. When a ship is steaming a straight course on a smooth sea at constant speed and with all external conditions which affect the torque also constant, the torque required to turn the propeller is approximately proportional to the square of the propeller rpm, and the horsepower required is

INTERLOCK	FUNCTION
A	THE REVERSER LEVER CAN NOT BE OPERATED UNLESS THE FIELD LEVER IS IN "OFF". THE FIELD LEVER CAN NOT BE OPERATED WHEN THE REVERSER LEVER IS IN "OFF"
B	THE TURBINE GOVERNOR LEVER CAN NOT BE MOVED BEYOND THE 2/3 SPEED POSITION WHEN THE REVERSER LEVER IS IN ASTERN.
C	THE TURBINE GOVERNOR LEVER CAN NOT BE MOVED BEYOND MANEUVERING SPEED UNLESS THE FIELD LEVER IS IN "RUN" EXCEPT THAT IF THE EMERGENCY LEVER IS IN STOP OR A SPEED CONTROL POSITION THIS INTERLOCK IS INEFFECTIVE. THE FIELD LEVER CAN NOT BE MOVED FROM THE RUN POSITION UNLESS THE TURBINE GOVERNOR LEVER IS IN "MANEUVERING" OR "SLOW SPEED", EXCEPT THAT IF THE EMERGENCY LEVER IS IN "STOP" OR SPEED CONTROL POSITION THIS INTERLOCK IS INEFFECTIVE. SEE NOTE 1 BELOW.
D	THE EMERGENCY LEVER CAN NOT BE MOVED TO A SPEED CONTROL POSITION UNLESS THE FIELD LEVER IS IN OTHER THAN THE "OFF" POSITION. THE FIELD LEVER CAN NOT BE MOVED TO "OFF" IF THE EMERGENCY LEVER IS IN A SPEED CONTROL POSITION.
E	THE SET-UP LEVER CAN NOT BE MOVED TO 2 MOTOR POSITION UNLESS THE REVERSER LEVER IS IN "OFF".
F	THE CUBICLE ACCESS DOOR CAN NOT BE OPENED UNLESS THE FIELD LEVER IS IN "OFF" AND THE SET-UP LEVER IN 1 MOTOR POSITION. THE FIELD LEVER CAN NOT BE MOVED FROM "OFF" OR THE SET-UP LEVER IN TO 2 MOTOR POSITION UNLESS THE CUBICLE DOOR IS CLOSED.
G	THE SET-UP LEVER CAN NOT BE MOVED IN TO 2 MOTOR POSITION UNLESS THE REVERSER IN THE OTHER ENGINE ROOM IS IN STOP. (ELECTRICAL)
H	THE REVERSER LEVER CAN NOT BE MOVED FROM THE STOP POSITION UNLESS THE REVERSER IN THE OTHER ENGINE ROOM IS IN STOP OR ONE OF THE TWO SET-UP LEVERS IS IN 1 MOTOR POSITION. (ELECTRICAL)

27.97

Figure 14-4.—Control lever interlocking.

11745

approximately proportional to the cube of the propeller rpm.

Thus for the main propulsion motors to meet the above requirements, their 3-phase stators must be supplied with a comparatively high voltage during induction motor starting periods and a voltage that is proportional to the frequency during synchronous operation. This necessitates overexciting the main propulsion generator fields during starts or reversals and a continuous adjustment of excitation at varying propeller speeds to ensure a constant volts per cycle output. This is accomplished by the voltage regulator acting in the control fields of the 3-kw amplidyne generator, as shown by figure 14-5.

Amplidyne fields F1-F2 and F7-F8 (fig. 14-5) are boosting fields. Field Fe-F4 is a bucking field. Field F7-F8 is excited from the ship's 120-volt d-c vital bus. Field F1-F2 is excited from a rectifier in the regulator unit. The a-c input to the rectifier is supplied from the secondary of the 2700/115 volt potential transformer whose primary is connected across the main propulsion generator output. Field F3-F4 (bucking field) is excited from the same potential transformer and another rectifier through a saturable reactor. When the voltage from the potential transformer secondary (the voltage being controlled) is low, the amplidyne boost fields predominate, but as the voltage rises, the reactor in series with the bucking field saturates causing a rapid rise in the bucking field strength. Thus an equilibrium is established between the fields, leaving a net boosting value of ampere turns sufficient to excite the amplidyne to hold 100 percent volts per cycle. Referring to figure 14-5, the complete sequence of operation of the system for one motor ahead is described below.

One-Motor Operation

In one-motor operation each motor is supplied simultaneously by its associated generator. Assume that the main propulsion turbine is running at idling speed, the auxiliary ship's service generators are supplying 450 volts a-c on the vital a-c bus, and 120 volts d-c on the vital d-c bus, and that the 60-kw exciter motor generator set is running. Assume the throttleman is in the after engineroom. The positions of the control levers are as follows:

Setup lever—one motor
Reverser lever—off
Field lever—off
Turbine govenor lever—maneuvering speed
Emergency turbine governor lever—normal
Turbine load limit handwheel—open
Exciter control switch—off

Turn the exciter control switch to the automatic position. This action connects the voltage regulator in the amplidyne field circuits and the armature output of the amplidyne to the 60-kw exciter field. Since the main propulsion generator field is open there will be little or no voltage from the potential transformer secondary and consequently amplidyne fields F1-F2 and F3-F4 will not be excited.

Field F7-F8 is excited from the 120-volt d-c vital bus through resistors R12-R14 to supply a small amount of boosting excitation just sufficient to raise the exciter voltage to a value which will ensure correct polarity and a fairly rapid rise of generator field current when the field lever is moved to position one.

Move the reverser lever to the ahead position. This action closes the main line contactors 1, 3, and 5 connecting the generator and motor with the proper phase sequence for ahead rotation.

Move the field lever to position one. The generator field contactor 21 closes and contactor 20 closes to bypass resistor R6 in the generator field circuit. Contactor F3 closes and F2 opens to insert maximum saturable reactor turns in series with amplidyne field F3-F4 allowing approximately 120 percent volts per cycle generator output. Contactors F4 and F5 close, increasing the excitation supplied to field F7-F8 to about 4 times its normal value. The amplidyne armature voltage increases to about 3 times normal, the exciter and main propulsion generator fields increase to a value approaching 3 times normal. During this time the main propulsion motor is starting as an induction motor. The motor field is not energized but is closed on itself through discharge resistor R5. This resistor is connected across the motor field only while the motor field contactor 22 is open. Discharge resistor R1 is connected across the generator field only while the generator field contactor 21 is open. Discharge resistor R8 is a special type thyrite resistor and is permanently connected across the exciter field. During the period while the motor is starting and accelerating as an induction motor, the line current indicated by the generator ammeter will increase rapidly and may go off scale. When the current decreases to approximately 1300 amperes, move the field lever to position two. Contactor 22 closes to energize the motor field

11745

11746

Figure 14-5.—Simplified schematic diagram of control circuits for one screw.

27.98

11747

through the synchronizing current limit resistor R2 to obtain proper conditions for synchronizing. Contactor 23 also closes. The voltage regulator continues to maintain 120 percent volts per cycle on the generator. As soon as the line current steadies, indicating that the motor has pulled into synchronism, move the field lever to the RUN position.

Contactor 24 now closes shorting out synchronizing resistor R2, and contactor 20 opens inserting resistor R6 in the generator field. This sets the proper relationship between generator and motor field current for normal operation. Contact F3 opens and contact F2 closes setting the volts per cycle held by the voltage regulator to the normal 100 percent value. The turbine governor lever can now be moved to increase speed as desired and the turbine load limit handwheel can be adjusted to give the desired steam flow.

NOTE: When the field lever is in position one and the motor is operating as an induction motor, the generator is highly overexcited; therefore, the motor should be synchronized as soon as possible. The field lever must not be left in position one for more than one minute.

Two-Motor Operation

Two-motor operation consists of both motors in parallel and supplied by one main propulsion generator. Control is excercised from the engineroom in which the active generator is located. The motor setup levers in both engine-rooms must be moved to the two-motor position. This action closes contactors 7, 8, and 9 paralleling the 3-phase stators of the two motors.

Contactors 14 and 15 close paralleling the motor fields. Contactor 13 closes inserting resistor R4 in parallel with synchronizing resistor R2 to provide proper motor field current adjustment for two-motor synchronization. As the two motors cannot be operated properly during the induction motor period with a common field discharge resistor, contactors 10 and 12 close and contactors 11 and 13 open allowing separate field discharge resistors. This circuit cannot be shown completely in the one line diagram in figure 14-5.

The control lever operating sequence is the same for two-motor operation as described for one-motor operation. The generator line current ammeter will go off scale during field lever positions one and two. As soon as the meter returns to scale the lever may be moved to the next position. About 80 percent of full speed is obtainable during two-motor operation (one generator).

Reversing or Stopping

To reverse or stop the drive system, return the turbine governor lever to the MANEUVERING SPEED position. Return the field lever to the OFF position without pausing in position ONE or TWO. With the reverser lever in the OFF position, pause for approximately 5 seconds and then move the reverser lever to the desired position. In the event of a crash stop or reversal, this pause should be omitted. Next, operate the field lever in the proper sequence for synchronizing to the RUN position. The turbine governor lever can now be operated to increase the speed as desired.

Manual Control of Excitation

In the event that the voltage regulator becomes inoperative, turn the standby excitation control switch 6 on the control panel (Fig. 14-3) to the MANUAL position. This action cuts the regulator out of the circuit so that the excitation can be controlled by means of the exciter field rheostat 29.

To prevent overloading the propulsion equipment when under manual control, do not exceed the generator field current values specified for the various speeds on the nameplate 3. The specified values of field current are maximum for safe continuous operation.

The change from automatic to manual control of excitation or vice versa can be made at any time. Before the change is made, however, the exciter field rheostat should be turned to the position that gives maximum generator field current. Immediately after the control is switched to manual, adjust the generator field current to the proper value corresponding to the propeller rpm indicated on the nameplate.

Ground or Phase Balance
Relay Operates

If a protective relay operates and trips open the propulsion field circuits, place the turbine governor lever in the MANEUVERING-SPEED position, return the field lever to the OFF position, return the reverser lever to the OFF position, remove the excitation and control power, and shut down the turbine generator by tripping the throttle valve.

11748

If the setup levers were in the TWO-MOTOR position at the time the relay operated, the setup levers should be returned to the ONE-MOTOR position. Remove the generator neutral ground connection by disconnecting the ground current limit resistor R9 (fig. 14-5). With all circuits deenergized use an insulation-resistance tester to locate the ground or fault. If the motors were operating in parallel at the time the relay operated, the fault may be in either motor circuit.

Emergency Excitation

If failure of one or both of the 60-kw propulsion exciter motor-generator sets occurs, an emergency connection can be made to utilize one of the 40-kw, 120-volt d-c ship's service generators to provide the necessary propulsion excitation. This emergency connection requires disconnecting the 60-kw exciter from the propulsion excitation bus and connecting the 40-kw ship's service generator through its circuit breaker to the propulsion excitation bus by a temporary cable. With this emergency connection the 40-kw generator will supply power to only the excitation bus in the same engineroom.

Thus, if one 60-kw propulsion exciter motor-generator set is out of service, the 40-kw ship's service generator in that engineroom can be connected to the propulsion excitation bus. The ship can then be operated at approximately full power with the regular propulsion exciter motor-generator set supplying propulsion excitation for one screw and the 40-kw d-c ship's service generator supplying emergency excitation for the other screw.

If both 60-kw propulsion exciter motor-generator sets are out of service, either the after or forward 40-kw generator can be connected to the corresponding propulsion excitation bus and one propulsion generator, to obtain two-motor operation.

Assume that the forward 40-kw ship's service generator is to be used to supply emergency excitation for the propulsion system (fig. 14-6). Operation of the ship will then be from the forward engine room using the forward propulsion generator and the two propulsion motors on two-motor operation. The ship's service a-c and d-c power must be obtained from the after engineroom. Similarly, the after 40-kw ship's service generator and after propulsion generator could be connected and operated. The forward ship's service generator would then be required to provide ship's service power.

It is obvious that both 40-kw ship's service generators cannot be used for propulsion excitation at the same time. Likewise, it will not be possible to use a remote ship's service generator for the excitation supply.

The operation of the propulsion plant will be different from normal and somewhat restricted because the 40-kw generator does not have as large an overload rating as the 60-kw exciter.

To connect the forward 40-kw generator to supply propulsion excitation, it is necessary to first have the after ship's service turbine-generator set warmed up and ready for operation. Then, in the forward engineroom, perform the following steps in sequence.

At the vital propulsion auxiliary panel, transfer all a-c and d-c loads to the remote source of vital power and open the excitation motor-generator circuit breaker.

At the ship's service generator and distribution switchboard, transfer all auxiliary a-c and d-c loads to the remote source of power. Open the a-c generator circuit breaker 1, open the generator field switch 2, open the d-c generator circuit breaker 3, open the d-c breaker for the forward vital propulsion auxiliary switchboard 4, open the d-c breaker for the after vital propulsion auxiliary switchboard 5, turn the 40-kw generator field rheostat 6 to minimum d-c volts, and open the d-c bus tie breaker 7. After testing for zero volts, open the disconnect switch links 8 on the load side of the d-c generator circuit breaker.

At the 60-kw exciter, disconnect the armature and field leads. Tape all the leads from the exciter and the two field line leads. Connect one end of the shore power cable to the armature line lead 9 and the other end to the disconnect link 8 at the switchboard. Be sure to maintain proper polarity. To reduce heating of the shore power cables, parallel two leads for one leg and use the third conductor for the other leg.

At the d-c restricted bus section of the forward ship's service and distribution switchboard, close the d-c bus-tie circuit breaker 7; close the 40-kw, d-c generator circuit breaker 3 and lock it; and adjust the propulsion excitation by means of the ship's service generator field rheostat 6.

A similar procedure is followed when connecting the after 40-kw generator to supply emergency power for propulsion excitation. When either 40-kw generator is used, very little torque will be available for starting or reversing because overexcitation (normally supplied to

11750

11749

Figure 14-6.—One-line diagram of emergency power for propulsion field excitation. 27.99

11750

11750

the generator field during starting) cannot be obtained from the 40-kw generator. However, if the operations are properly executed, one motor can be started and synchronized successfully even though the ship is dead in the water. One motor can be successfully reversed when there is a small headway on the ship. During starting and reversing, the current from the 40-kw generator will exceed the rating of the machine for short intervals of time. As soon as possible after synchronizing, the propulsion generator excitation current should be reduced to the recommended value for manual control of excitation.

To START and RUN one motor, move the propulsion control levers to the positions for normal starting on one motor. Turn the standby excitation control switch to the MANUAL position. Be certain that the 40-kw generator is running at rated speed. Raise the d-c generator volts as high as possible by means of the d-c generator field rheostat (this voltage can be read as exciter volts on the propulsion control panel). Place the field lever in position ONE. When the shaft rpm and line current are steady. move the field lever quickly from position ONE to the RUN position without pausing in position TWO. The propulsion motor should synchronize and run.

Lower the excitation voltage until the propulsion generator field current corresponds to the specified value for the existing propeller rpm. Adjust the propeller rpm by means of the turbine governor lever. When raising the propeller rpm, watch the 40-kw generator current. When it reaches 330 amperes, the propeller rpm (and therefore the propulsion generator field current) should not be raised any further. The idle propeller will turn unless locked. If allowed to turn, be certain that lubricating oil is supplied to the thrust block and line shaft bearing.

To reverse the direction of the ship when operating on one motor, drop the propeller rpm to 100 or less and allow the ship to settle down to this speed. Place the turbine governor lever in the MANEUVERING-SPEED position. Move the field lever to the OFF position. Move the reverser lever in the desired direction. Raise the d-c generator volts as high as possible by the d-c generator field rheostat.

Place the field lever in position ONE. When the shaft rpm and line current are steady, move the field lever quickly from position ONE to the RUN position without pausing in position TWO. The propulsion motor should synchronize and run.

Lower the excitation voltage until the propulsion generator field current corresponds to the specified value for the existing propeller rpm. Adjust the propeller rpm by means of the turbine governor lever. When raising the propeller rpm, watch the 40-kw generator current and do not allow it to exceed 330 amperes.

To run on two motors with reduced excitation for the turbogenerator in use, first get the ship underway on one motor. Raise the speed until the idle propeller turns without power. Remove power from the active screw and allow the ship to slow down until both propeller rpms are equal. Move the setup levers in both engine-rooms to the TWO-MOTOR position. Restart the motors, as previously explained, for ONE-MOTOR operation.

Adjust the propeller rpm by means of the turbine governor lever. Adjust the propulsion generator field current to the value specified for manual excitation control. When raising the propeller rpm do not permit the 40-kw generator current to go beyond 330 amperes.

A reversal of the direction of the ship should not be attempted when operating on two motors. Reversal can be accomplished when operating on two motors, however, by placing both setup levers to the ONE-MOTOR position and allowing the shafts to slow to 100 rpm and then follow the procedures previously explained for reversal on one motor.

Emergency Blocking of Electrical Interlocks

The electrical interlocks previously described can be blocked out manually in an emergency when control power is lost.

If control power is lost in the forward engineroom and it is desired to operate on one motor alone, the forward engineroom reverser interlock must be blocked out.

If it is desired to operate on two motors and the after engineroom is to control, the forward engineroom setup lever interlock must be blocked out. The reverser in the forward engineroom must be left in the OFF position. On the other hand, if the forward engineroom is to control, the forward engineroom setup lever interlock and the reverser interlock must be blocked out. The reverser in the after engineroom must be left in the OFF position.

The propulsion system requires routine maintenance to keep it in reliable operating

11751

11751

condition. Figures 14-7 and 14-8 show the maintenance requirement cards for a representative a-c propulsion generator and propulsion motor, respectively. Note that these cards cover only the weekly requirements and that each requires less than one hour to complete, with two men assigned to perform the work. The propulsion generators and motors are vital to the operation of the ship and must be maintained in a high state of readiness for operation. Simple cleaning and testing procedures as shown by the maintenance requirement cards will permit you to spot minor troubles and prevent what could develop into serious damage to vital and costly equipment.

DIESEL ELECTRIC D-C PROPULSION INSTALLATION

A representative diesel electric d-c propulsion installation in a U.S. fleet tug consists of four diesel engine-driven propulsion generators, which furnish power through the control equipment to one propulsion motor, which in turn drives the propeller. Each generator is provided with an exciter mounted on an extension of the generator shaft. The four generating units are located amidship, two on the port side and two on the starboard side.

The propulsion motor is directly connected to a single propeller shaft and located on the

PROCEDURE

NOTE 1: Measure insulation resistance weekly, when securing, and before starting, if idle for more than a week.

Preliminary

a. Wire air starting/steam inlet valve shut and tag "Do Not Open."
b. On electric start system, disconnect starting motor at battery terminals and tag "Out Of Service."
c. Ensure excitation supply switches are open and tagged "Out Of Service."
d. De-energize all power supplies to cubicle /switchboard and tag "Out Of Service."

(Cont'd on Page 2)

LOCATION | DATE 16 August 1965

Procedure (Cont'd)

1. Clean and Inspect Slip Rings.
   a. Open or remove access covers.
   b. Set multimeter on appropriate scale and test to ensure all power supplies are de-energized.
   c. Wipe slip rings and housing with a rag.
   d. Inspect slip rings for pits, grooves, and corrosion. Clean, if necessary.

2. Measure Insulation Resistance.

NOTE 2: Use megger to measure insulation resistance.

a. Measure field insulation resistance at slip rings.

NOTE 3: If insulation resistance is less than 1.0 megohm for stator or 0.5 megohm for field, take corrective action.

b. Open or remove access covers of cubicle/switchboard.

WARNING: Wear 5000/7000-volt rubber gloves and have safety man standing by.

c. Set multimeter on appropriate scale and test to ensure all power supplies are de-energized.
d. Measure stator insulation resistance. See NOTE 3.
e. Ensure no loose items are left inside unit.
f. Close or reinstall access covers.
g. Remove wire or reconnect starting motor.
h. Remove tags and set up for prescribed operation.

centerline of the ship in a separate compartment immediately aft of the generating units.

The control equipment consists of an engineroom control station and a pilothouse control station with instrument panel. A transfer switch is provided to control the drive system from either the engineroom or the pilothouse. The control provides for controlling the outputs of the four propulsion generators and associated exciters, and the speed and direction of rotation of the propulsion motor.

The diesel engines and generators rotate in the same direction for both ahead and astern rotation of the propeller. Primary control of the direction and speed of the propeller rotation is obtained by changing the polarity and magnitude of the generator terminal voltage. The polarity and magnitude of the generator terminal voltage are changed by controlling the direction and magnitude of the generator field current. The speed over certain ranges is also controlled by varying the speed of the diesel engines and associated generators.

The control is effected by means of a speed controller in the engineroom or by a speed controller in the pilothouse. The speed controller is connected to a rheostat and reversing contacts for controlling the magnitude and direction of the generator field current and to an engine speed transmitter for controlling the engine speed.

7. 1/2"-drive Socket set
8. 6" Normal duty screwdriver
9. 5000/7000-volt Rubber gloves

PROCEDURE

NOTE 1: Measure insulation resistance weekly, when securing, and before starting, if idle for more than a week.

Preliminary
a. Ensure motor starting lever/set-up handwheel is in the OFF position; tag "Out Of Service."
b. Ensure excitation supply switches are open; tag "Out Of Service."
c. De-energize all power supplies to cubicle/switchboard and tag "Out Of Service."

1. Clean and Inspect Slip Rings.
a. Open or remove access covers.
b. Set multimeter on appropriate scale and test to ensure all power supplies are de-energized.
c. Wipe slip rings and housing with a rag.

(Cont'd on Page 2)

LOCATION | DATE: 16 August 1965

Procedure (Cont'd)

d. Inspect slip rings for pits, grooves, and corrosion. Clean, if necessary.

2. Measure Insulation Resistance.

NOTE 2: Use megger to measure insulation resistance.

a. Measure field insulation resistance at slip rings.

NOTE 3: If insulation resistance is less than 1.0 megohm for stator or 0.5 megohm for field, take corrective action.

b. Open or remove access covers of cubicle/switchboard.

WARNING: Wear 5000/7000-volt rubber gloves and have safety man standing by.

c. Set multimeter on appropriate scale and test to ensure all power supplies are de-energized.
d. Measure stator insulation resistance. See NOTE 3.
e. Ensure no loose items are left inside unit.
f. Close or reinstall access covers.
g. Remove tags and set up for prescribed operation.

98.176

Figure 14-8.—Weekly MRC for A-C propulsion motor.

11753

The system is designed to permit operation of any combination from one to four generators with the motor. Also, either generator 2 or 3 but not both at the same time, can be used to supply auxiliary power for salvage operations. When this is done the generator cannot be used in propulsion service.

PROPULSION GENERATORS

The four propulsion generators are d-c, separately excited, 2-wire, split-frame, self-ventilated machines. They are heavy duty marine type units designed for operation over the speed range of the diesel engines. Commutating poles are provided to improve commutation. Each generator is rated at 610 kw, 375 volts, 1625 amperes, and 700 rpm.

PROPULSION EXCITERS

As previously stated, each propulsion generator is equipped with a directly connected exciter, which provides excitation for the associated generator field. The exciters are d-c, separately excited, 2-wire, self-ventilated units provided with commutating poles. Each exciter is rated at 3 kw, 70 volts, 43 amperes, and 350/700 rpm.

PROPULSION MOTOR

The propulsion motor is a d-c, separately excited, adjustable speed motor having commutating and compensating windings (fig. 14-9). It is actually two identical motors with their armatures mounted on a common shaft. The armatures are operated in series at all times. Each half of the motor is rated at 1500 horsepower, 750 volts, 1610 amperes, and at 112/140 rpm. The power is supplied from the propulsion generators, which are connected with their armatures interposed with those of the propulsion motor so that the maximum voltage across any part of the propulsion loop does not exceed 750 volts. The shunt type fields of the propulsion motor are excited from the ship's 240-volt (auxiliary), d-c supply. The two armatures are mounted on a single shaft with their commutators adjacent. The direction of rotation is determined by viewing the commutator end of each armature. The stator frames are independently foot mounted and are also identical except for the brush rigging and the polarities of the shunt field leads, which are made to suit the opposite direction of rotation of the armatures.

77.228

Figure 14-9.—Propulsion motor.

The propulsion motor is designed so that either armature can be conveniently bridged to remove it from the propulsion loop in the event of an emergency. When one armature is removed from the propulsion circuit, the capacity of the motor is reduced one-half, and not more than two generating units should be operated for propulsion service.

The propulsion motor is provided with induced ventilation by means of a separately mounted blower through a duct connected to an opening in the enclosing cover of the commutator at the top of the machines. The air is drawn in through openings in the end bells at both ends of the motor and flows through radial ducts in the armature cores, over the armature surfaces and between the field coils where it passes over the commutators and out the opening at the top.

11753

11754

The blower is driven by a 15-horsepower, 230-volt stabilized shunt, d-c motor. The motor is controlled by a magnetic starter (mounted in a separate cabinet), which is controlled from the main propulsion control board. The starter is equipped with a START-STOP pushbutton for local operation.

PROPULSION CONTROL EQUIPMENT

The propulsion control equipment (fig. 14-10) is assembled as a unit and located on the platform level in the engineroom. The indicating instruments and the handles of the manually operated devices are mounted on the front of three 2-section panels that comprise the control board. The first two are the generator panels and the third is the motor panel. The third panel does, however, mount some devices that are not directly associated with control of the propulsion motor. Referring to figure 14-10, the four voltmeters M1 mounted on the generator panels indicate the voltages of the four main propulsion generators. The two exciter voltmeters M2 indicate the voltages of the four exciter generators. One voltmeter is for exciters 1 and 2 and one is for exciters 3 and 4. These voltmeters are also used as ground detectors. The two exciter voltmeter and ground detector transfer switches SW1 are used to transfer the two voltmeters to the circuits whose voltages are to be read. The excitation voltmeter M9 indicates the voltage of the ship's 240-volt d-c supply. This voltmeter is also used as a ground detector.

The excitation voltmeter and generator field ground detector transfer switch SW4 are used to transfer the voltmeter to the various circuits. The auxiliary power ammeter M3 on the first generator panel indicates the current supplied to the auxiliary power circuits by the generator being used to furnish auxiliary power.

The four engine speed indicators M5 indicate the speeds of the four diesel engines. The auxiliary power control switch SW2 operates the auxiliary field contactor which energizes the exciter field circuit of the generator supplying auxiliary power. The auxiliary power generator field rheostat RH1 is provided to control the strength of the exciter field of the generator supplying auxiliary power.

The four small handwheels SW11 are the generator control switches that control the field circuits of the four generators and associated exciters to apply or remove excitation. The four large handwheels SW9 and SW10 control the setup switches of the four generators. The switching arrangement is such that generators 1 and 4 may be used only for propulsion service, whereas generators 2 and 3 may be used for either propulsion or auxiliary power service. Operating in conjunction with each generator setup switch, is an engine speed-exciter field setup switch SW5, not shown in figure 14-10.

The motor voltmeter M4 mounted on the motor panel indicates the voltage across the two motor armatures and also functions as a ground detector in the generator and motor armature circuits. The motor voltmeter and ground detector transfer switch SW3 is used to transfer the voltmeter to the circuits to be read.

The motor field ammeter M6 indicates the current in the motor field circuits. The motor ammeter M8 indicates the current in the propulsion circuit.

The control transfer switch SW8 is provided to transfer control of the propulsion system from the engineroom to the pilot house.

The excitation control switch SW7 operates the exciter contactor which energizes the exciter and motor fields from the ship's 240-volt d-c supply.

The motor field rheostat handwheel RH2 controls the excitation of the motor field. Engineroom controller handwheel P1 controls the operation of the propulsion system from the engineroom. The controller has 24 ahead and 24 astern speed operating positions. An emergency stop-release button is located at the 22nd controller position. The operator must press the release button to move the controller beyond this point.

OPERATION

By the use of disconnect blocks (fig. 14-11 part 1) either motor armature may be bridged and removed from the propulsion loop in an emergency. When one armature is removed the motor voltage rating is reduced one-half, consequently not more than two generators should be operated in the series propulsion loop.

The overload relays OR1 and OR2 are designed to operate in case of a short circuit in the propulsion or auxiliary power circuit. When a short circuit occurs in the propulsion circuit, relay OR1 closes its contacts and energizes the tripping coil for excitation contactor K2, (part 4). When a short circuit occurs

in the auxiliary power circuit, relay field contactor K1.

The two resistors R11 in series with RH 2 (part 2) and the two motor fields are provided to adjust the excitation of the motor fields so that the two motor armatures divide their loads equally. As the two armatures are identical the excitation currents should be approximately the

11756

11755

same. Once correctly adjusted, these resistors need not be changed.

Adjustable resistors R4 in the exciter field circuits are provided to equalize the performance characteristics of the generators as they, too, need not be changed after they are properly adjusted. Motor field discharge resistor R10 (part 2) is connected across the motor fields only while the excitation contactor K2 is in the open position. Exciter field discharge resistors R2 are connected across the exciter fields while the associated generator setup switch SW5 is in the OFF position. The main propulsion generator field discharge resistors R1 are thyrite resistors and are permanently connected across the generator fields. An engine speed transmitter rheostat RH5 (part 3) is provided with the engineroom and pilot house controllers. These two transmitters consist of three rheostats mounted together and operated by a common shaft, which is a projection of the propulsion controller operating shaft (fig. 14-12). The three rheostats are adjusted so that each has a different value for any controller position and are connected to a receiver on the engine speed govenor.

A third transmitter, the auxiliary power engine speed transmitter RH6, mounted behind the generator panels, controls the speed of the diesel engine which is being used to supply auxiliary power. This transmitter has a fixed setting and each time the transmitter assumes control the engine speed is brought to the predetermined value of 450 rpm.

The engine speed circuits are series circuits. For this reason loading resistors R5 and R6 (fig. 14-16 part 3) are provided to maintain the circiut resistance constant, thereby keeping the synchros in calibration. The resistors are switched in and out of the circuit by the generator setup switches SW5.

Starting

Before starting the system determine that the engineroom controller and the pilot house controller are in the STOP position; the excitation control switch SW7 (fig. 14-16, part 4) is in the OFF position; the engine speed control switch SW6 (part 3) is in the OPEN position; the auxiliary power control switch SW2 (part 4) is in the OFF position; the auxiliary power generator field rheostat RH1 (part 2) is in the MAXIMUM RESISTANCE position, and the generator setup switches SW9 and SW10 (part 1), and the generator control switches SW11 (part 2) are in the OFF position. (This does not apply to a generator already in auxiliary power service.) Assume the system is to be controlled from the pilot house.

To start the system, turn the handwheel of each generator setup switch SW9 and SW10 to the position corresponding to the service that the generator is to supply. This action connects the main propulsion generator and motor armatures in a closed series propulsion loop. Setup switches SW5 operating in conjunction with SW9 and SW10 close contacts 14 and 16 (part 2) in the exciter field circuits whose generators are selected for propulsion service and contacts 2, 4, 6, 8, 10, 11, and 12 (part 3) in the engine speed circuits for the associated engines.

NOTE: Generators 2 and 3 setup switches are interlocked so that only one or the other may be placed in the auxiliary power position at a time; also a setup switch cannot be moved from the propulsion to auxiliary power position unless the associated generator control switch SW11 is in the OFF position. Place the motor field rheostat RH2 (part 2) in the position corresponding to the number of generators to be put in service.

Close the generator control switches SW11 of the generators to be operated. This action closes relays K4 and K5 in the respective exciter and generator field circuits. Start the diesel engines to be used. The engine speeds should reach and remain at 350 rpm. Turn the control transfer switch SW8 to the PILOT HOUSE position. (This switch cannot be moved to transfer control unless the excitation control switch SW7 is in the OFF position.)

Contacts 16 and 18 (part 4), contacts 20, 22, 24, 26, and 28 (part 3) and contacts 2, 4, 6, 8, 10, 12, and 14 (part 2), close. Contacts X (part 4), are closed only while the controller is in the STOP position. Close the excitation control switch SW7 (part 4). This action completes the circuit to the excitation contactor K2 closing coil (part 4) and the excitation contactor K2 (part 2), closes and latches, making available the ship's 240-volt d-c power for control and excitation. Excitation contactor K2 will not close unless the controller selected by the control transfer switch is in the STOP position. The circuit to the motor field weakening contactor coil (part 4), is also completed at this time and the K3 relay operates opening the K3 contact (part 2) allowing light excitation to be applied to the motor fields while the controller is in the STOP position. Place the exciter voltmeter and ground detector switch, SW4 (fig. 14-10) in the first position to determine

Figure 14-12.—Engine speed transmitter and receiver.

by voltmeter, M9, that the 240-volt d-c supply is available.

Close the engine speed control switch, SW6 (fig. 14-11, part 3) to apply 240-volt d-c power for operation of the engine speed control system. Place the two exciter voltmeter and ground detector transfer switches, SW1 (fig. 14-10), in the first position. In this position the two exciter voltmeters, M2, will indicate the exciter voltages for two of the exciters. Later the switches can be placed in the second position to check the voltages of the other two exciters. Move the pilot house controller clockwise to the first position in the ahead direction of propulsion.

This action closes contacts AH1 and AH2 (fig. 14-11, part 2) to apply light excitation to the fields of the generators in the propulsion service. Contact X (part 4), opens to deenergize the motor field weakening relay K3, and contact K3 (part 2), closes. Excitation to the motor fields is not determined by the setting of the motor field rheostat, RH2. This motor field excitation is held constant throughout the controller range.

Current now flows in the generator and motor armature circuits causing the propeller to rotate slowly in the ahead direction. Moving the controller up to the 11th position progressively accelerates the propeller speed by increasing the generator excitation, the engine speeds remaining at 350 rpm. Moving the controller from the 12th to the 24th position accelerates the propeller speed by increasing the speed of the diesel engines while holding the generator excitation constant. To prevent the exciters from building up the excitation of the generators with increased speed, the controller inserts blocks of resistance in the exciter field circuits when progressing from the 12th to the 24th controller position. When the maximum rated engine speed of 700 rpm is reached, the output of the system is maximum.

Stopping

To stop the ship from underway in the ahead direction, slowly move the controller handwheel counterclockwise to the STOP position, observing the motor ammeter, M8, in the propulsion circuit. If the controller is moved too rapidly toward the stop position, the motor will tend momentarily to act as a generator, causing the generators to act as motors and hold the engine speed for a time above the speed called for by the controller position. No useful purpose can be gained by bringing the controller too rapidly to the STOP position. When the STOP position is reached, advance the controller gradually step-by-step counterclockwise in the astern direction until the propeller exerts the desired amount of retarding force. When the ship has come to rest, return the controller to the STOP position.

Reversing

When the controller handwheel is turned counterclockwise for astern rotation, the same operating conditions exist as for the corresponding position in the ahead direction, except the current flow is reversed in the excitation circuits of the exciters by contacts AS1 and AS2 (fig. 14-11, part 2), and, hence, a reversal occurs in the motor and generator armature circuits.

11760

To reverse the ship from underway in the ahead direction to underway in the astern direction, follow the same procedures for stopping the ship. Continue advancing the controller in the counterclockwise direction for astern propulsion until the desired propelling speed is obtained. An astern ship speed for this type ship should not exceed 10 knots because of the limitations of the steering gear.

Removing Generator From Propulsion Service

The controller is not necessarily moved to the STOP position to cut a generator in or out of the propulsion circuit. However, under normal conditions, the controller should be moved to the 11th position so that the engines are operating at the idling speed of 350 rpm. In an extreme emergency a generator can be cut out of the circuit while the engine is above the idling speed because the generators are designed to withstand short circuiting a full rated speed of 700 rpm with no field current on the generator.

If it is necessary to cut out a generator, open control switch SW11, then pause several seconds to allow the generator field current to decay to zero before operating the associated setup switch, SW9, or SW10. This time interval is necessary for the generator field excitation to decrease sufficiently to avoid the possibility of motoring the generator and to reduce the current surges in the propulsion circuit to a minimum.

Placing Generator in Propulsion Service

Before cutting an additional generator in the propulsion circuit, the motor field rheostat, RH2, must be adjusted to the correct setting for the total number of generators to be operated in propulsion service. For example, if two generators are in service and another machine is required in the propulsion loop, set the motor field rheostat at the correct position for the operation of the generators before cutting in the third machine. This action is essential and if not performed will result in greatly overloading the diesel engines, generators, and motor immediately when the third generator is cut in the circuit. The effect of this overloading can be serious. Therefore, always adjust the motor field rheostat, RH2, for the number of generators that are to be used and then cut the generators in the circuit one at a time, as previously explained.

Placing Generator in Auxiliary Power Service

To place a generator in auxiliary power service, turn the setup switch, SW10, of either generator 2 or 3 to the AUXILIARY POWER position. This will connect the generator output to the auxiliary power bus, 8 and 9 (fig. 14-11, part 1). Associated setup switch, SW5, will close contact 1, 3, 5, 7, 9, 11, and 12 (part 3), bringing the associated diesel engine under the control of the auxiliary power engine speed transmitter, RH6, which brings the engine speed to 450 rpm, as mentioned previously.

Contacts 13 and 15 (part 2) in the exciter field circuit for the generator selected will also close (contacts 14 and 16 remaining open). Close the generator control switch, SW11, of the generator to be used, which will close contactors K4 and K5. Remember the setup switch, SW10, cannot be moved from the auxiliary power position to the propulsion position unless this generator control switch, SW11, is first turned to the OFF position. Close the auxiliary power control switch, SW2 (part 4), energizing the auxiliary power field contactor, K1, which will close contact, K1 (part 2). The generator voltage may now be adjusted to normal by the auxiliary power rheostat, RH1.

D-C propulsion systems require routine weekly maintenance as shown by the maintenance requirement cards (figs. 14-13 and 14-14) for a d-c propulsion generator and motor, respectively. Note the a-c propulsion system weekly maintenance requires two men, note only one EM3 is required to do the weekly maintenance on the d-c propulsion system.

Also note the differences in the minimum allowable resistance readings as shown on figures 14-7 and 14-8 and figures 14-13 and 14-14. The d-c propulsion generators and motors require a complete quarterly cleaning and inspection as shown by the maintenance requirement cards 14-15 and 14-16, whereas the a-c propulsion system requires cleaning weekly and semi-annually.

The maintenance requirement cards shown do not cover all the required maintenance for electric propulsion systems, they cover only the cleaning, inspection, and resistance readings of the major units, the propulsion generators,

CAUTION: Do not damage windings.

(Cont'd on Page 2)

LOCATION | DATE 2 August 1965

PAGE 1 OF 3 | MB | ZZZG | GGO | 75 | B709 | Q

Procedure (Cont'd)

a. Remove access covers.
b. Test with voltage tester to ensure all power supplies are de-energized.
c. Vacuum accessible parts; use dusting brush to loosen dirt in hard-to-reach areas.

WARNING: Ensure at least two persons are in the work area when using inhibited methyl chloroform. Provide adequate ventilation.

CAUTION: Keep inhibited methyl chloroform from coming in contact with commutator and brushes.

d. Use a rag dampened with inhibited methyl chloroform to remove oily deposits.
e. Inspect brushes for uniform wear, condition of brush shunts, and shunt connections.
f. Remove and inspect brushes. Renew any brush that measures less than half its original length or is chipped or worn to such an extent that it will not travel freely in the holder. Inspect the brush contact area for proper contact surface. Wipe brushes and brush holders with a dry rag.
g. Clean commutator risers; use a tongue depressor or suitable small wedge wrapped in one thickness of rag.

NOTE 1: Commutator color will vary with conditions. Long periods at light load or improper spring tension will change the film. A full power reversal will sometimes cause burned spots along a row of brushes, but these will disappear after about a week of normal running.

h. Inspect commutator for pits, burrs, and grooving. Correct as necessary.
i. Adjust brush holders to the same distance from commutator, not more than 1/8" or less than 3/32".

CAUTION: If 10 percent of brushes are worn short, renew all brushes.

NOTE 2: Use BuShips-approved brushes and all of the same grade.

CAUTION: Do not snap springs in place, as this may crack or chip the brushes.

(Cont'd on Page 3)

PAGE 2 OF 3 | MB | ZZZG | GGO | 75 | B709 | Q

Procedure (Cont'd)

j. Reinstall brushes. Ensure they travel freely in the holders.

NOTE 3: Ensure new brushes are properly seated.

k. Adjust brush pressure from _____ to _____ ounces.
l. Inspect armature fans for loose, cracked, or broken parts. Correct as necessary.
m. Inspect all electrical and mechanical fastenings and tighten loose connections. Use lockwashers or jamnuts, where necessary, to keep connections tight.
n. Measure insulation resistance of armature and field circuits. See MRC W-1.

NOTE 4: Never apply varnish to a dirty surface. Avoid building up excess varnish.

o. Inspect for chipped, cracked, or frayed insulation. Touch up with air-drying varnish, where necessary.
p. Ensure no loose items are left inside generator.
q. Reinstall access covers.
r. Remove wire or reconnect starting motor.
s. Remove tags and set up for prescribed operation.

M.R. DESCRIPTION

1. Clean and inspect motor.

SAFETY PRECAUTIONS

1. Observe standard safety precautions.
2. Ensure motor disconnect device is open; tag "Out Of Service."
3. De-energize all power supplies and tag "Out Of Service."
4. Avoid prolonged contact with, or inhalation of, inhibited methyl chloroform. Provide adequate ventilation.

TOOLS, PARTS, MATERIALS, TEST EQUIPMENT

1. Tongue depressor
2. Air-drying varnish
3. Brush tension scale
4. 1/2" Drive socket set
5. 6" Normal duty screwdriver
6. Inhibited methyl chloroform
7. Rags
8. 6" Scale
9. Flashlight
10. Safety tags
11. 1" Paintbrush
12. 4/0 Sandpaper
13. Dusting brush
14. Vacuum cleaner
15. Voltage tester
16. 500-volt Megger

PROCEDURE

Preliminary

a. Ensure motor disconnect device is open; tag "Out Of Service."
b. De-energize excitation circuit and tag "Out Of Service."
c. De-energize heaters and inspection lights, if installed, and tag "Out Of Service."

1. Clean and Inspect Motor.

CAUTION: Do not damage windings.

a. Remove access covers.
b. Test with voltage tester to ensure all power supplies are de-energized.

(Cont'd on Page 2)

LOCATION | DATE 2 August 1965

PAGE 1 OF 3 | MB | 222G | MDO | 75 | B711 | Q

Procedure (Cont'd)

c. Vacuum accessible parts; use dusting brush to loosen dirt in hard-to-reach areas.

WARNING: Ensure at least two persons are in the work area when using inhibited methyl chloroform. Provide adequate ventilation.

CAUTION: Keep inhibited methyl chloroform from coming in contact with commutator and brushes.

d. Use a rag dampened with inhibited methyl chloroform to remove oily deposits.
e. Inspect brushes for uniform wear, condition of brush shunts, and shunt connections.
f. Remove and inspect brushes. Renew any brush that measures less than half its original length or is chipped or worn to such an extent that it will not travel freely in the holder. Inspect the brush contact area for proper contact surface. Wipe brushes and brush holders with a dry rag.
g. Clean commutator risers; use a tongue depressor or suitable small wedge wrapped in one thickness of rag.

NOTE 1: Commutator color will vary with conditions. Long periods at light load or improper spring tension will change the film. A full power reversal will sometimes cause burned spots along a row of brushes, but these will disappear after about a week of normal running.

h. Inspect commutator for pits, burrs, and grooving. Correct as necessary.
i. Adjust brush holders to the same distance from commutator not more than 1/8" or less than 3/32".

CAUTION: If 10 percent of brushes are worn short, renew all brushes.

NOTE 2: Use BuShips approved brushes and all of the same grade.

CAUTION: Do not snap springs in place, this may crack or chip the brushes.

j. Reinstall brushes. Ensure they travel freely in the holders.

(Cont'd on Page 3)

PAGE 2 OF 3 | MB | 222G | MDO | 75 | B711 | Q

Procedure (Cont'd)

NOTE 3: Ensure new brushes are properly seated.

k. Adjust brush pressure to_____to_____oz.
l. Inspect armature fans for loose, cracked, or broken parts. Correct as necessary.
m. Inspect all electrical and mechanical fastenings and tighten loose connections. Use lockwashers or jamnuts, where necessary, to keep connections tight.
n. Measure insulation resistance of armature and field circuits. See NRC W-1.

NOTE 4: Never apply varnish to a dirty surface. Avoid building up excess varnish.

o. Inspect for chipped, cracked, or frayed insulation. Touch up with air-drying varnish, where necessary.
p. Ensure no loose items are left inside motor.
q. Reinstall access covers.
r. Remove tags and set up for prescribed operation.

CHAPTER 15

RECORDS AND REPORTS

Records are those papers required to be compiled and retained on board ship for prescribed periods of time for reference in administrative and operational matters. Reports are summaries or narratives submitted to interested activities to assist in forming policy, controlling operations, evaluating performance, and maintaining historical records. Some reports are required to be submitted at set intervals, and are referred to as recurring reports. Other reports are submitted only on the occurrence of a given situation, and are referred to as one-time reports.

The engineer officer is responsible for maintaining various records and submitting various reports concerning the engineering department. As an EM 3 or 2 you will be required to maintain certain records concerning the electrical equipment. This chapter discusses those records that concern you. Discussed also are various technical publications that contain valuable information for Electrician's Mates.

MAINTENANCE AND MATERIAL MANAGEMENT SYSTEM (3-M)

The maintenance and material management (3-M) system discussed in chapter 2 of this course) will eventually be installed on every ship in the Navy. At this time however, some ships have the 3-M system and some have partial installation of 3-M; others have not started the system as yet. Some ships that have the 3-M system are deleting some of the paperwork involved in keeping the old type material history, while other ships are keeping both the 3-M and material history. The decision to still maintain or delete some of the material history entries after installation of the 3-M system is made by the type commanders of the various forces. Since many naval ships do not as yet have the 3-M system and some that do have it are still required to maintain the material history and CSMP, the following coverage is included.

MATERIAL HISTORY AND CSMP RECORDS

The material history and current ship's maintenance project (CSMP) records provide a record of all repairs, alterations, inspections, derangements, parts renewed, hours in use, and other pertinent data on each machinery unit. These records are perhaps the most valuable records in the engineering department. The records are kept on cards filed in looseleaf binders. The following material history and CSMP record cards are available for maintaining the records.

- NavShips 527—Machinery history
- NavShips 527A—Material history card - electrical
- NavShips 528—Unit record card
- NavShips 529—Repair record card (CSMP)
- NavShips 530—Alteration record card (CSMP)
- NavShips 531-1 (10-63)—Resistance test record - power, lighting, and degaussing circuits
- NavShips 531 (Rev. 8-48)—Resistance test record - electrical rotating machinery
- NavShips 532—Blank utility card
- NavShips 533—Bearing record
- NavShips 536—Electronic equipment history card
- NavShips 537—Record of field changes (CSMP)
- NavShips 539—Hull history card

Cards NavShips 536 and 537 concern electronic equipment and are maintained by the operations department. As an Electrician's Mate you will be concerned with material

11766

history cards NavShips 527A, 531-1, and 531, and CSMP cards NavShips 529 and 530.

NAVSHIPS 527A

A separate Material History Card-Electrical, NavShips 527A (fig. 15-1) is maintained for each major unit of electrical equipment. The history recorded on the card should include a record of all tests and measurements such as full load tests and air gap measurements; a record of all troubles, failures, and methods used to restore the equipment to service; dates showing when the equipment was greased; and of all repairs affected whether by by ship's force or a repair activity. When a card for a particular unit is full (front and back) the history is continued on another card.

To fill out the NavShips 527A proceed as follows: Numbers referred to correspond to those circled in figure 15-1.

1. Enter in this space the machinery index number (S group number) of the unit for which the card is being prepared.
2. Name of the unit.
3. Service the unit performs.
4. Original cards are number 1, and additional cards are numbered consecutively.

5, 6, 7, and 8. Enter in these spaces the location of the unit as to deck, frame, name and number of compartment, and position (port, stbd, or center line).

9 through 15. These spaces are self-explanatory.

16, 17, and 18. Enter in these spaces the part, group, and page number of the Revised Individual Allowance List (RIAL) where the unit is listed. This page of the RIAL contains the complete nameplate data for the unit. If the ship uses the Coordinated Shipboard Allowance List (COSAL) enter NA (not applicable) in these spaces.

19. Enter in this space the NavShips number of the manufacturer's technical manual for the unit.
20. Enter the CID number for the unit if the ship uses the COSAL. This number identifies the allowance parts list in the COSAL where the unit is listed.
21. Enter CD sheet No. if applicable. This sheet contains data concerning the unit not included on the MFG or BuShips drawing.
22. Enter here any ShipAlts applicable to the unit.

The entries under "Remarks" should be in chronological order. Make your remarks as specific and clear as possible. List federal stock numbers for all parts used for repairs.

Enter in the "Hrs. in use" space the number of hours the unit has been in operation since the last major overhaul. This applies only to major equipments such as ship's service and emergency generators, main propulsion motors and generators, steering gear motors, motor-generator sets, and degaussing equipment.

NAVSHIPS 531-1 (10-63) and 531 (Rev. 8-48)

Resistance test record cards (531-1) are maintained for each power, lighting, and degaussing circuit as previously discussed in chapter 3 of this training course. The resistance test record card 531 (rev. 8-48) is maintained on each piece of rotating electrical equipment. Figure 15-2 shows a typical resistance test record card for a propulsion generator.

CURRENT SHIP'S MAINTENANCE PROJECT (CSMP)

The CSMP is a method of tabulating all outstanding repairs and alterations as well as periodic tests and inspections that can only be accomplished during a scheduled upkeep or overhaul period. The primary purpose of the CSMP is to ensure that no item of work will be overlooked and to facilitate the planing of shipyard and tender work requests. The secondary purpose of the CSMP is to provide data for the material history. A CSMP is normally maintained by each department of a ship and may consist of those items that can only be accomplished by a shipyard or tender. Repair items that are performed by the ship's force as soon as possible after being discovered are normally handled by a memorandum work request; use of the Repair Record is optional, data for the Material History being obtained from the work request.

The following three basic cards comprise the CSMP:

1. Repair Record, NavShips 529 (blue).
2. Alteration Record, NavShips 530 (pink).
3. Record of Field Changes (to electronic equipment) NavShips 537 (white).

8.105

Figure 15-1.—Material history card-Electrical NavShips 527-A.

As a repair is required, or an alteration or field change is authorized, the applicable card is filled in and placed in the material history binder adjacent to the appropriate history card. As the binder is examined, the distinctive colors of the CSMP cards readily indicate outstanding work. When the work has been completed and notations to this effect entered on the material history card, all the cards except the Record of Field Changes are removed from the binder and placed in a "completed work" file.

Repair Record Cards and Alteration Record Cards are retained for a period of two years after the work is completed and entries made in the material history. After the two-year period, these cards may be destroyed at the discretion of the commanding officer. When a ship is decommissioned or placed out of service, the active cards are retained onboard the ship.

NavShips 529

The Repair Record card, NavShips 529 (fig. 15-3) is filled in as soon as the need for the repair becomes evident.

Entries on this card are as follows: (Numbers listed correspond to the circled numbers on the card shown in figure 15-3.

1. An "X" to indicate the type of repair work. (It will be mechanical, electrical, or hull for the engineering department's work.)
2. The number and the name of the unit on which the repair is to be made. This information can be obtained from the corresponding Electrical History card.
3. The index number, taken from the corresponding Electrical History Card, for the unit to be repaired.

11768

1.3

Figure 15-2.—Resistance Test Record, NavShips 531 (Rev. 8-48).

4, 5, and 6. An "X" indicates the priority of the repair (deferred, routine, or urgent) assigned by the ship.

7. The location of the unit to be repaired. The compartment name and number should be given. Where necessary, the location in the compartment and frame numbers are given.

8. Date the card is started. (The card should be started when the need for the repair is first noticed.)

9. Originally, this space was provided for the title to which a repair was charged. This information is no longer applicable.

10, 11, and 12. An "X" indicates whether the work is to be performed by the ship's force, by the repair ship, or by the naval shipyard.

13. A brief description of the condition of the item to be repaired. List any authorizing reference for the work to be done if applicable.

14. State specifically what work is to be done to effect the repair. If the repair is to be done by a repair activity, include what assistance will be given by the ship's force, and the name of at least one individual who can be contacted for additional information concerning the repair.

15, 16, and 17. Repair parts known to be needed, plan no. of such part or parts if applicable, and federal stock no. for parts.

18, 19, 20, and 21. These spaces are self-explanatory.

22. The Board of Inspection and Survey item number, if such an inspection has been held. This number is entered on the Repair Record Card when a list of repairs is made for an inspection by the Board of Inspection and Survey.

11770

11770

23. The title of the type, or force, commander convening a forces afloat material inspection, if such an inspection has been held.
24. The number of the quarter and the year in which the forces afloat inspection was held.
25. The forces afloat material inspection item number, when applicable. This number is entered on the Repair Record Card when a list of repairs is made up for a material inspection.
26. The file number of any letter that may have been received or written in regard to the repair item. A copy of this letter, when sent, is placed in the log room file.
27. The date of such a letter (No. 26).
28. On the back of the card (fig. 15-3B) the file number of any reply to a letter that may have been written (No. 26).
29. The date of such a reply (No. 26).
30. The job order number if the repair is to be done by a repair activity.
31. For repair jobs that have not been fully completed by a repair activity by the end of the availability. Enter the percentage of completion for reference for the next availability.
32, 33, 34, 35, and 36. These spaces are self-explanatory.

NavShips 530

The Alteration Record Card, (fig. 15-4), is used to record all authorized alterations pending. While an alteration is pending the card is placed behind the Electrical History Card of the unit affected, with the pink tab extending above the top of the history card.

Entries that should appear on this card are based on information contained in the SHIPALTS which are sent to the ship concerned, and these entries are similar to those on the Repair Record Card. There is this difference in recording information on the two cards: the Repair Record Card is made

out when the need for a repair becomes evident, or when it is decided that a repair should be undertaken at a future date; the Alteration Record Card, on the other hand, is filled out upon receipt of the approved SHIPALT. Space is provided on the back of card (not shown) for describing the work done to complete the alteration.

MAINTENANCE RECORDS

Electrician's Mates are required to maintain a number of maintenance records, such as ground test sheets, storage battery tray records, periodic tests and inspections, work request records, and others. These records at present are kept on official NavShips forms, forms prepared by type commanders, and forms prepared by the engineering department of the individual ship concerned.

GROUND TEST SHEETS

Ground test sheets are prepared by the individual ship. They should include the following information:

1. Name of the circuit or unit to be tested.
2. Frequency of tests (weekly, monthly, or quarterly).
3. Location of circuit or unit to be tested.
4. Insulation resistance reading in megohms of the circuit or unit tested.
5. Initials of the man making the test.
6. Date readings are transferred to the NavShips 531 card.

NAVSHIPS 151

The Storage Battery Tray Record, NavShips 151 (fig. 15-5) is a complete history of each lead-acid storage battery aboard ship. The record is normally kept up to date by the battery electrician, and includes the battery number, nameplate data, record of service, and charges. The back of the record (not shown) provides spaces for test discharge data and repairs.

In addition to NavShips 151, a battery charging and discharging record and a weekly pilot cell reading record are required. These records are prepared by the individual ship concerned.

SHIP'S MEMORANDUM WORK REQUEST

The Ship's Memorandum Work Request (fig. 15-6) is an interdepartmental form used by any department that requires work to be performed by another department. This memorandum ensures the proper routing of work requests between heads of departments. The work requests list the work to be done and include an estimate of the man-hours and material required to complete the job. Space is provided also for the shop that performs the work to list the material used, the man-hours expended, the date of completion, and the approximate cost. Similar forms are filled in when a ship requires work to be done by a shipyard or tender.

LEGAL RECORDS

The Engineer's Bell Book and the Engineering Log are official legal records. They can be used in any military or civilian court as final proof of any action taken on or by the ship, and as evidence for or against any officer or enlisted man of the ship's crew who may be brought before the court or board.

The Engineer's Bell Book (NavShips 116, fig. 15-7) is a record of all bells, signals and orders, and of the time they are received regarding the movement of the ship's propellers. The entries are generally made by the throttleman. However, when entering or leaving port, or during any maneuvering activity the entries should be made by an assistant. This procedure permits the throttleman to give full attention to the signals.

The engineering officer of the watch, before going off duty, must sign the Bell Book in the line following the last entry for his watch and the next officer of the watch must continue the record immediately thereafter. In machinery spaces where an engineering officer of the watch is not stationed, this record must be signed by the senior petty officer of the watch. Alterations or erasures are not permitted. An incorrect entry must be corrected by drawing a single line through it and making the correct entry on the following line. Such deleted entries must be initialed by the engineering officer of the watch, senior petty officer of the watch, or O.O.D. (in the case of ships and craft equipped with controllable reversible pitch propellers) as appropriate.

Figure 15—5.—Storage battery tray record, NavShips 151.

The records for each throttle control station for each day must begin with a new sheet, and the day's records for all stations must be clipped together and filed as a unit.

Instructions for keeping the Engineer's Bell Book are as follows:

1. A separate sheet shall be used for each shaft each date except on small ships and craft where the keeping of separate sheets for separate shafts is not practicable. All sheets for the same date should be filed together as a single record. (Entries in the Bell Book shall be made at the time of receipt of each order.)

2. In column 1, times shall be entered according to the system used in the Engineering Log.

3. In column 2, enter the signal received.

a. If the signal is transmitted by the engine (motor) order telegraph, use the following symbols:

Z—stop
1/3—ahead one-third speed
2/3—ahead two-thirds speed
I—ahead standard speed
II—ahead full speed
III—ahead flank speed

Backing signals for 1/3 and 2/3 speed shall be entered as "B 1/3" and "B 2/3", respectively. Signals for full back and emergency back shall be entered as "BF" and "BEM", respectively. On small ships and

WORK REQUEST
(SHIP'S FORCE)

CL83 - 6/24/49

Date 7 May 19—

FROM: Electrical Officer

TO: Repair Off., R Div. Off., First Lt. or CHBOSN.

1. It is requested that the following work be accomplished.

Item upon which work is to be done:	Location:	J.O. Number:
Battle Telephone System - 49 JY	Mount 40-7	413-52

Work to be done: (Furnish sketch, dimensions, plans, etc., where applicable.)

Cut off old 20 wire connection box mounted on gun shield. Manufacture brackets to fit new switch box and weld in place. Dimensions of brackets to be taken from work.

Work to be inspected / ~~received~~ by: Whaley I. C.C.

11775

craft, using a single sheet for two or more shafts, the above symbols shall be used with an additional preceding symbol "P," "S," or "C" (for port, starboard, or center shaft, respectively) if the signal is directed to other than all shafts.

b. If the signal is transmitted by the engine revolution telegraph without change in the engine (motor) order telegraph, the number of propeller revolutions signaled shall be entered in column 2. In this case, entries shall not be made in column 3.

4. An entry in column 3 shall be made for all signals received on the engine order telegraph and shall be the propeller corresponding to the engine order telegraph signal. When a signal is received simultaneously on the engine order telegraph and the engine revolution telegraph, appropriate entries shall be made in both column 2 and column 3.

5. The rpm entries in either column 2 or column 3 are the propeller rpm ordered; not rpm resulting from the order.

6. In column 4 enter the engine counter reading at the time the change is made. Also, enter the counter reading each hour on the hour.

The Engineering Log (NavShips 117) is a midnight-to-midnight daily record of the ship's engineering department. It is a complete daily record, by watches, of important events and data pertaining to the engineering department and the operation of the ship's propulsion plant. The log must show the average hourly speed in revolutions and knots, the total engine miles steamed for the day, and all major speed changes; draft and displacement; fuel, water, and lubricating oil on hand, received and expended; the engines, boilers, and principal auxiliaries in use, and all changes therein. All injuries to personnel occurring within the department and casualties to material assigned to the department, and such other matters as may be specified by competent authority, are entered into the engineering log.

The original entries in the log, neatly prepared in pencil or ink, is the legal record. The remarks must be prepared and signed by the engineering officer of the watch, or day, before leaving his station or being relieved. Any errors must be overlined and initialed by the person preparing the original entries.

The engineer officer must verify the accuracy and completeness of the entries and sign the log daily. The commanding officer must sign the log on the last calendar day of each month, and on the date of relinquishing command.

The Engineer's Bell Book and the Engineering Log must be preserved as a permanent record on board for a three-year period unless they are requested by a naval court or board, or the Navy Department. In such a case, a copy (preferably photostatic) of such sheets that are sent away from the ship are prepared and certified as a true copy by the engineer officer for the ship's files. At the end of the three-year period these records may be destroyed. When a ship is stricken, if either record is less than three years old, it should be forwarded to the nearest Naval Records Management Center.

OPERATING RECORDS

A constant check of all machinery and units in operation must be made by the men on watch in the machinery spaces. The data obtained by the watchstanders is entered on records referred to as operating records. These records, in addition to ensuring frequent observation of all machinery in operation, provide a basis for analyzing machinery performance.

Operating records that will concern you are the Electrical Log-Ship's Service Electric Plant, NavShips 3649, and the A-C/D-C Electrical Propulsion Operating Record, NavShips 3647.

NAVSHIPS 3649

The Electrical Log, NavShips 3649 (fig. 15-8) is a complete daily record (from midnight to midnight) of the operating conditions of the ship's service electric plant. The log sheet must be kept clean and neat. Any corrections or changes to entries for a watch must be made by the man that signs the log for that watch. However, corrections or additions must not be made after the log sheet has been signed by the engineer officer without his permission or direction. The station logs are turned in to the log room every morning for the engineer officer's signature and for filing.

Figure 15-8.—Electrical Log-Ships service electrical plant, NavShips 3649.

The back of the log (not shown) is a continuation of the front, and also provides spaces for the engineer officer's and senior Electrician's Mate's signatures.

NAVSHIPS 3647

The A-C/D-C Electric Propulsion Operating Record, NavShips 3647 (fig. 15-9 A&B), is used on all surface ships equipped with a-c or d-c electric drive. The record is maintained by the Electrician's Mate standing the throttle watch. Spaces are provided on both the front and the back for data concerning the main propulsion equipment.

The general instructions for keeping this record are the same as those mentioned previously for the NavShips 3649.

EQUIPAGE AND REPAIR PARTS RECORDS

The basic types of material aboard ship are (1) consumable supplies, (2) equipage, (3) repair parts, and (4) ship's machinery and equipment. As an EM 3 or 2 you may be assigned division supply petty officer. This duty will require you to use the ship's allowance list in requisitioning consumable supplies and repair parts for the division. You may also be called upon to assist in the inventory of the electrical repair parts and equipage. Allowance lists, requisitioning material, inventories, and the associated forms and records are discussed in Chapter 12 of Military Requirements for Petty Officer 3 & 2, NavPers 100056-B.

MISCELLANEOUS RECORDS

Additional records that you may be required to maintain are listed below.

DEGAUSSING RECORDS

Degaussing records are contained in the degaussing folder, NavShips 1009, discussed in chapter 12 of this training course.

11777

TESTS OF SAFETY DEVICES

A record of the weekly tests of all electrical safety devices.

TROUBLE CALL RECORD

A record of electrical trouble calls showing the time of the call, nature of trouble, men assigned, and the time the trouble was corrected.

ROUGH WORKBOOKS

Rough workbooks are ledger type notebooks maintained by the men in charge of a particular shop, space, or circuit. They should contain rough notes on a day-by-day basis of all work done. Material and repair parts used should be recorded along with sufficient details concerning repairs to support appropriate entries on the Material History Card, NavShips 527A. Rough workbooks should be kept up to date, and as neat as possible.

TECHNICAL PUBLICATIONS

The Naval Ship Systems Command publishes various technical publications concerning the operation and maintenance of electrical and electronic equipment. Publications of interest to Electrician's Mates include the NavShips Technical Manual, Naval Ship Systems Command Technical News, Manufacturers' technical manuals, Ship Information Books, Damage Control Books, and others.

NAVSHIPS TECHNICAL MANUAL

The NavShips Technical Manual is one of the most important Naval Ship Systems Command publications. This manual contains the administrative and engineering instructions for the use of the engineering department. It describes methods of conducting tests, procedures for making repairs, and many helpful maintenance suggestions. It is the official authority on operating procedures.

As an Electrician's Mate, you should be familiar with the following chapters of the NavShips Technical Manual.

Chapter New No.	Chapter Old No.	Title
9003	4	Allowance, surveys, and requests for material
9004	6	Inspections, records, and reports
9200	20	Winches and capstans
9220	22	Steering gear
9310	31	Spare parts
9340	34	Commissary equipment
9005	40	Tables of engineering data
9410	41	Main propelling machinery, section IV
9450	45	Lubricants and lubrication systems
9600	60	Electric plant--general
9610	61	Electric generators and voltage regulators
9621	62	Electric Power Distribution System
9622	62	Portable Storage Batteries and Dry Batteries
9630	63	Electric motors and controllers
9640	64	Lighting
9660	66	Searchlights
9690	69	Electrical measuring and test instruments
9810	81	Mine protection, section III
9830	83	Elevators
9880	88	Damage control, section III, part 2

MANUFACTURERS' TECHNICAL MANUALS

Manufacturers' technical manuals provide detailed information concerning the operation and maintenance of specific equipment. They are, in most cases, prepared by the manufacturers of the equipment concerned. Military Specification MIL-M-15071E, of 15 April 1962, establishes four types of manufacturers' technical manuals and provides instructions for their preparation. The types of manuals are: type 1, electrical and mechanical; type 2, electronic and special equipment; type 2a, experimental equipment; and type 3, systems.

You will be using the type 1 manual. The material in this manual is arranged in the following order:

1. Front matter

11779

2. Section one—general information
3. Section two—installation
4. Section three—operation
5. Section four—troubleshooting
6. Section five—maintenance
7. Section six—parts list
8. Index

When a piece of equipment is installed and the technical manual is not received the installation should not be accepted as complete.

SHIP INFORMATION BOOK, VOLUMES 3 AND 5

The General Specifications for Ships of the United States Navy required that the building shipyard for each combatant ship and many larger auxiliary ships, furnish to each such ship it builds copies of Volumes 3 and 5 of the Ship Information Book. Volume 3, Power and Lighting Systems, of the Ship Information Book serves a particular ship, and replaces the Record of Electrical Installations and Electrically Operated Auxiliaries, previously required. Volume 3 consists of two parts. Part 1 contains a general description, and design information of each electrical auxiliary and equipment. Part 2 contains the manufacturers' and shipbuilder's test data. This part is particularly valuable as a basis for comparison of test results obtained after the equipment has operated over a period of time. Volume 5 of the Ship Information Book covers the interior communication and fire control systems. As an EM3 or 2 you may find this volume helpful in assisting the IC gang.

DAMAGE CONTROL BOOKS

Damage control books are furnished to all combatant, miscellaneous, and auxiliary ships over 220 feet in length, and to certain smaller fleet-operated ships. A detailed description of the damage control book is set forth in chapter 9880, of NavShips Technical Manual.

ADDITIONAL PUBLICATIONS

Additional publications that contain valuable information for Electrician's Mates are NavShips Standard Electrical Symbol List, NavShip 0960-000-4000, Lighting on Naval Ships, NavShips 250-560-4, and the Cable Comparison Guide, NavShips 250-660-23.

APPENDIX I

TRAINING FILM LIST

Training films that are directly related to the information presented in this training course are listed below. Under each chapter number and title the training films are briefly described. Other training films that may be of interest are listed in the United States Navy Film Catalog, NavWeps 10-1-777.

The films listed in appendix 1 are unclassified. The information listed after the title gives date of film release, color or B/W (black and white), run time in minutes, and indicates either sound or silent film.

Example:

1962	B/W	16 min	Sound
Release date	Color	Run Time	Sound/Silent

Chapter 1

ADVANCEMENT

MN 8990 115 Volts—Deadly Shipmate. (1960—Color—19 min.—Sound) Reenactment of actual accident cases. Emphasizes the disastrous effects of low voltage electrical shock when basic rules of electrical safety are violated or ignored.

Chapter 2

THE 3-M SYSTEM

MN 9958A Planned Maintenance System—Concept. (1963—color—24 min—sound) Implements OPNAVINST 4700.16.

MN 9958B Planned Maintenance System—Application. (1963—B&W—12 min—sound) Use in shipboard maintenance.

Chapter 4

SHIPBOARD LIGHTING

ME 8445 Electrical Circuit Faults. (1945—B&W—19 min—sound) How to test for and locate common circuit faults.

11781

SEMICONDUCTOR DEVICES: (Continued)

TEMPERATURE DEPENDENT DIODE

PNPN SWITCH

TUNNEL DIODE

TYPICAL ELECTRON TUBES:

COLD CATHODE GAS TUBE

PHOTOTUBE SINGLE UNIT, VACUUM

RECTANGULAR

RIDGED

ROTARY JOINT

DIRECTIONAL COUPLERS

GENERAL

E PLANE APERTURE COUPLING, 30 DB TRANSMISSION LOSS

COUPLING METHODS:

GENERALLY USED FOR COAXIAL AND WAVEGUIDE TRANSMISSION.

COUPLING BY APERTURE WITH AN OPENING OF LESS THAN FULL WAVEGUIDE SIZE. TYPE OF COUPLING WILL BE INDICATED WITHIN CIRCLE (E, H, OR HE).

COUPLING BY LOOP TO SPACE

COUPLING BY LOOP TO GUIDED TRANSMISSION PATH

COUPLING BY PROBE FROM COAXIAL TO RECTANGULAR WAVEGUIDE WITH DIRECT-CURRENT GROUNDS CONNECTED

TYPICAL MAGNETRONS AND KLYSTRONS:

REFLEX KLYSTRON, APERTURE COUPLED

TUNABLE MAGNETRON, APERTURE COUPLED

1175

Chapters 6

MAINTENANCE OF MOTORS AND GENERATORS

MN 9333 Electrical Maintenance. (1952—B&W—15 min—sound) Emphasizes safety in electrical maintenance.

MC 7356 Commutation of D-C Machines. (1951—B&W—24 min—sound) Theory and maintenance.

MA 9697A Motors and Generators—Part 1—D-C-Motor and Generators. (1961—B&W—35 min—sound) Principles of operation.

MA 9697B Motors and Generators—Part 2—A-C Motors and Generators. (1961—B&W—25 min—sound) Design, characteristics, and operation.

Chapter 7

BATTERIES

MN 2333C Electricity and Magnetism—Part 3 Voltaic Cell, Dry Cell, and Storage Battery. (1943—B&W—18 min—sound) Shows basic principles of the Voltaic Cell, storage batteries, and dry cells. Explains what a cell does when current is being used, internal resistance and method of checking and recharging a battery. Demonstrates combining of materials affecting the voltage and method of increasing voltage.

MA-2333D Electricity and Magnetism—Part 4—Charging Storage batteries. (1943—B&W—15 min—sound) Explains by animation, what happens when a battery is charged, and how to bring a battery back to full charge, how to tell if the battery is overcharging, constant current method of charging a battery, and how to prepare electrolyte in the field.

MA-8371 Why Battery Should Always Be Clean. (1955—B/W—6 min—sound) How to clean battery—washing, wiping dry, checking electrolyte level, greasing terminals.

MN-8592 Theory of Lead-Acid Storage Battery. (1959—B&W—25 min—sound) How chemical energy is converted into electrical energy, to produce electromotive force.

Chapter 9

CONTROL DEVICES

MN-3485F Electric Power Afloat-Operating A-C and D-C Motors and Controllers. (1945—B&W—16 min—sound) Animation and diagrams present operating principles of a-c and d-c motors and controllers. Shows how to perform daily, operational, and periodic checks of the mechanisms. Demonstrates how to operate and maintain the motors and and explains emergency procedures in the event of operational failure.

11782

11781

Chapter 11

POWER DISTRIBUTION

SN-3485C Electric Power Afloat—Starting and Applying Load. (1945—B&W—12 min—sound) Using 2200 destroyer as an example, shown general placement of forward and after generators and relates them to their prime movers, the steam turbines. Detail steps in starting generator, and in making inspections before starting turbo generator, are included in the films.

MN-3485E Electric Power Afloat—Operating—Direct Current Generators. (1945—B&W—15 min—sound) Illustrates main units of the Direct current generator, switchboard, and devices of the panel. Demonstrates step-by-step procedure for starting generator no. 1, performing prestart run, paralleling generators 1 and 2, and securing. Animation shows flow of current in the units.

Chapter 12

ELECTRIC AUXILIARIES

MN 6731A Shipboard Degaussing Systems—Installations. (1952—B&W—20 min—sound) Installations of shipboard degaussing systems are discussed under four headings: theory of degaussing, installation procedures, tests and installation certificates.

MN 6731B Shipboard Degaussing Systems—Operation and Maintenance. (1952—B&W—20 min—sound) Demonstrates the operation of shipboard degaussing systems, ranging, preventive maintenance, and inspections.

MN 6731C Shipboard Degaussing Systems—Compass Compensation. (1952—B&W—20 min—sound) Demonstrates how to compensate the magnetic compass for the effects produced by degaussing coils. Discussion is taken up under four headings: theory, installation, compensation, and swing for deviation.

MN 9679A EMS Magnetometer Controlled Degaussing System-Principles Of Operation. (1962—B&W—22 min—sound) How to set up equipment for shipboard operation.

MN 9679B EMS Magnetometer Controlled Degaussing System-Maintenance and Repair. (1962—B&W—15 min—sound) Preventive maintenance and repair. Can be applied to EMS 1-4 and GEM 2 and 3 units.

MN 8208 Electrohydraulic Steering Gear. (1956—B&W—15 min—sound) Explains functions of the components of the electrohydraulic steering system aboard ship. Demonstrates the operation of the electrical type transmission linkage to the dual power unit, the differential control of the hydraulic pump, and the delivery of power to the hydraulic rams.

11784

11783

Chapter 13

GYROCOMPASSES

MN 1792C The Gyro-Compass—The Gyroscope and Gravitation. (1944—B&W—12 min—sound) Theory and operation of pendulous and mercury ballistic type compasses. Effect of gravity upon gyroscope.

MN 1792D The Gyro-Compass—The Gyro Becomes A Compass. (1944—B&W—15 min—sound) Models of pendulous and mercury ballistic type compasses to explain why gyroscope turns toward the meridian. How its motion is damped, and how it is kept on the meridian.

MN 1792E The Gyro-Compass—The Compass System. (1944—B&W—16 min—sound) Five assemblies—sensitive, phantom, and spider elements mercury ballistic and binnacle of a Sperry mark 14 gyro compass. Operation of follow-up and repeater systems.

Chapter 14

ELECTRIC PROPULSION INSTALLATION

MN 2385B Turbine-Electric AC Drive (Destroyer Escort)-Operation—Part I. (1944—B&W—15 min—sound) Setting up propulsion equipment before and during first part of the turbine warm-up period is demonstrated. Teaches correct names of the operating levers and switches, and various instruments which give indications of operation of the equipment. Schematic drawings review principles of operation of this drive.

MN 2385C Turbine-Electric AC Drive (Destroyer Escort)-Operation—Part 2. (1944—B&W—23 min—sound) Operations for getting underway and method of testing propulsion motors are taught. Demonstrates procedures to start moving ahead, increasing or decreasing speed, and stopping. Engine-room duties when underway are covered.

MN-2385D Turbine-Electric AC Drive (Destroyer Escort)-Operation Notes. (1944—B&W—15 min—sound) Function of the interlocks, their importance, and procedures for operating in slow and top speed ranges are explained. Operation in full speed astern is observed. Function and operation of load limit handwheel are shown.

MN-2385E Turbine-Electric AC Drive (Destroyer Escort)-Operation in Case of Casualty-Part 1. (1944—B/W—17 min—sound) Illustrates some of the methods that have been found practical in meeting casualties on the DE and maintaining the transmission of power to the screws.

MN 2385F Turbine-Electric AC Drive (Destroyer Escort)-Operation in Case of Casualty-Part 2. (1944—B/W—18 min—sound) Continuation of MN-2385E, illustrating methods that have been found practical in meeting casualties on the DE and keeping power to the screws. Deals with operation when there is trouble in the electrical equipment.

11784

11783

Chapter 15

RECORDS AND REPORTS

FN-7849A Material History Records—Introduction. (1955—B&W— 13 min—sound) How to maintain the material history records.

FN-7849C Material History Records—Electrical Record Cards. (1955—B&W—9 min—sound) Describes the Electrical History Card and the Resistance Test Card. Shows how to find the right card, how to use it and how to keep it up to date.

FN 7849E Material History Record—Repair Record Card. (1956—B&W—10 min—sound) Describes the repair card and its use in a current ship's maintenance project. Covers the proper notation of basic information on the need for a repair, progress information while the job is being done and entries when the job is complete.

FN 7849F Material History Records—Alteration Record Card. (1955—B&W—11 min—sound) Describes the Alteration Record Card and the step by step procedure of its use before, during and after a typical alteration.

APPENDIX III
GREEK ALPHABET

Name	Capital	Lower Case	Designates
Alpha	A	α	Angles.
Beta	B	β	Angles, flux density.
Gamma . . .	Γ	γ	Conductivity.
Delta	Δ	δ	Variation of a quantity, increment.
Epsilon . . .	E	ϵ	Base of natural logarithms (2.71828).
Zeta	Z	ζ	Impedance, coefficients, coordinates.
Eta	H	η	Hysteresis coefficient, efficiency, magnetizing force.
Theta	Θ	θ	Phase angle.
Iota	I	ι	
Kappa	K	κ	Dielectric constant, coupling coefficient, susceptibility.
Lambda . . .	Λ	λ	Wavelength.
Mu	M	μ	Permeability, micro, amplification factor.
Nu	N	ν	Reluctivity.
Xi	Ξ	ξ	
Omicron . . .	O	o	
Pi	Π	π	3.1416
Rho	P	ρ	Resistivity.
Sigma	Σ	σ	
Tau	T	τ	Time constant, time-phase displacement.
Upsilon . . .	Υ	υ	
Phi	Φ	φ	Angles, magnetic flux.
Chi	X	χ	
Psi	Ψ	ψ	Dielectric flux, phase difference.
Omega	Ω	ω	Ohms (capital), angular velocity ($2 \pi f$).

School Housekeeping. A Guide for the Modern Custodian.

Tennessee Univ., Knoxville. School Planning Lab.
MF AVAILABLE IN VT-ERIC SET.
The University of Tennessee, The School Planning Laboratory, College of Education, P.O. Box 8530, Knoxville, Tennessee 37916 ($7.50).
PUB DATE - 70 107p.

DESCRIPTORS - *RESOURCE MATERIALS; *TRADE AND INDUSTRIAL EDUCATION; *CUSTODIAN TRAINING; *SCHOOL MAINTENANCE; ADULT VOCATIONAL EDUCATION

ABSTRACT - Intended primarily as a reference guide for school custodians, this guide also presents school administrators and teachers with information on proper maintenance and cleaning procedures essential to keeping school facilities safe and sanitary. In addition to a chapter on selection, training, and responsibilities of the school custodian, contents cover: (1) general information on cleaning procedures, materials, and equipment, (2) care of restroom facilities, (3) maintenance and care of hard floors, (4) maintenance and care of carpets, and (5) climate control, including heating, air conditioning, and ventilation. Suggested time schedules for performance of tasks are provided for each section. (AW)

11797

INTRODUCTION

This guide was prepared to assist school board members, superintendents, principals, teachers, custodians, and other personnel charged with the responsibility of keeping school facilities clean and safe for students. The need for this manual is compounded because of the increasing importance being placed upon the modern school custodian.

The physical environment of the school has a direct effect on the behavior and learning responses of students. Cleanliness is a vital part of this environment; therefore, the importance of this guide is indispensable if proper care and cleaning procedures of school facilities are to be assured.

This manual was prepared as a reference guide primarily for custodians. It also attempts to serve as a means to acquaint the school administration with the various responsibilities of the modern custodian. In bold outline, it presents essential information needed by school personnel in regards to proper cleaning and maintenance procedures. The physical composition of school buildings is made up virtually of every type building material,

11798

which makes proper cleanliness extremely complicated. Significant tenets of proper cleaning, cleaning materials, and suggested time schedules are stressed in this guide. Additional information is included on the treatment of materials and equipment, safety, and the proper care of special facilities, ranging from the care of carpet to the total plant itself.

It is hoped that this guide may be of assistance to the many progressive schools which are becoming fully cognizant of the importance that an immaculate facility has on the implementation of a successful educational program.

11799

PREFACE

This book is a welcome addition to the few existing publications intended to be directly useful to the custodial staff of a school plant. Only in recent years have educators realized the great impact that building custodians have on the morale of staff and students. Proper attention to the maintenance of such factors as safety, cleanliness, climate control, and aesthetic appearance are in evidence in any good teaching-learning situation; and where they are in evidence there is always a quality custodial staff.

The great advances in school planning now in progress have resulted in innovative, functional school plants which use a great variety of materials and equipment. These changes demand an equally great variety in the kinds of custodial practices, and a generally higher level of custodial competence. Educators are now faced with a new set of problems regarding custodial care such as: a program of continuing re-education for the custodian, diversification in duties and developing a custodial staff team concept, and securing adequate materials, supplies and equipment specifically designed to meet new custodial needs.

11800

Supply companies have been quick to respond to new requirements, thus providing administrators an opportunity to make wise choices in providing for the needs of their custodial staff.

This manual reflects the combined wisdom of many years of experience. Each of the contributors is an experienced teacher or administrator with considerable experience in school planning and in the effective use and maintenance of school plants. Their combined experience permits them to view custodial problems from such positions as teacher, principal, superintendent, school plant director, and college business manager. All have worked together as research associates in the University of Tennessee School Planning Laboratory.

The manual is direct in its approach to the problems of school building custodial care and management. Revision of such a manual is inevitable since new materials and equipment will become obsolescent with accelerating advances in school plant planning. In the meantime, this manual should be a must in every school and school system. Its proper use should result in enhancing the functional and aesthetic qualities of the educational environment and in the custodial staff receiving justly deserved recognition and respect.

CHAPTER I

SELECTION, TRAINING, AND GENERAL RESPONSIBILITIES OF THE CUSTODIAN

The custodian is enmeshed in a rapidly changing occupation due to new materials, methods, and demands being forced upon him by a dynamic educational scene. The fact that larger sums of money are now being expended on school plant construction, and that these buildings are greater in size, value and complexity make it necessary for a corresponding improvement in the caliber of men serving as custodians. It is the purpose of this chapter to enumerate some general attributes and responsibilities, as well as some guidelines in selecting the "modern" custodian.

Custodians are responsible to the principal. Systems large enough to justify the establishment of adequate supervision from the central office over custodial services have an advantage in that such supervision will usually establish better methods and standards of work and check on adequate performance. In most systems, however, the principal, as head of the school, is directly responsible for the total operation and success of his

11805

institution. The custodian in these cases often becomes the principal's right hand man. This type of principal usually recognizes how important the custodial role is and appreciates the fact that a clean, well kept, and properly heated and ventilated building influences favorably the teaching and learning process. The custodian in return respects the wishes of the principal and carries out his suggestions and requests, and assists in every way possible to assure a clean and well-organized building.

The relationship should be friendly, courteous and obliging. Part of the custodian's responsibility is to serve teachers and pupils. He must also treat these people with courtesy and respect; with a sense of friendliness being maintained in a dignified, professional manner. From time to time, teachers and pupils will ask the custodian to do a special task in connection with their school work. The custodian should strive to assist them in a cheerful and pleasant manner without lamentation, and without attempting to excuse himself from such additional duties. Although a teacher or a principal may occasionally appear caustic, the custodian should attempt to overlook this. Teachers occasionally become nervous and irritable when working with 30

11806

active, peppy and sometimes mischievous children. At a time like this, a pleasant obliging attitude on the part of the custodian may help to cheer her up.

There will be times when a custodian must enter a classroom during recitation and study periods. He must do so quickly and quietly and perform whatever task necessary with as little disturbance as possible.

Since it is part of the custodian's job to serve teachers, there will be times when he must alter his routine and go out of his way to see that they are accommodated. For instance, if a teacher keeps pupils in after school for a special reason, the custodian should avoid going into the room at that time to do his routine cleaning. There may be other times when a teacher is working alone in her room after school and would not want to be disturbed. Even though his work is extremely important, in most cases it is up to the custodian to accommodate the teacher, rather than the teacher accommodate the custodian. As a general rule, however, the teacher will usually cooperate with the custodian and not interfere with the performance of his duties. Should a teacher try to monopolize a custodian's time, it is up to the principal, not the custodian, to tactfully correct the situation.

11807

Relationships with pupils should be friendly and pleasant but should not destroy the adult-child relationship. By being friendly and earning the respect of the pupils, the custodian will find them cooperating with him in his work. It must be remembered that it is the responsibility of the teacher to correct or give direction to pupils and not the custodian.

The custodian is a part of the public relations program. There will be many occasions when it is necessary for the school to be open after regular school hours for school or community events. An obliging, helpful and friendly attitude on the part of the custodian will do much to establish rapport between the school and community.

School Custodian. Normally, the custodian is entrusted with the community's largest single investment. But the responsibility doesn't stop with the care of the school building; it includes the safety, health, and comfort of all persons who utilize the building. A good custodian is not just a person who cleans the building; he is all of the above and more. A custodian who is fully meeting his responsibility is a man of many talents; but his importance is probably

11808

underestimated more by the custodian himself than by others. The good custodian must believe in himself and in the job he is doing. If he has a personality that attracts the respect and appreciation of his fellow workers and students, he will usually find they are more likely to cooperate with him in carrying out his duties.

CHARACTERISTICS OF A GOOD CUSTODIAN

1. A custodian believes in himself and in the importance of his job.
2. The custodian is dependable and punctual.
3. The custodian is loyal to his school and his fellow workers.
4. The custodian is fair, friendly, and impartial in his dealings with others.
5. The custodian is courteous and pleasant.
6. The custodian has few, if any, objectionable traits.
7. The custodian is a peaceful and loyal citizen in the community.
8. The custodian wears conservative work clothes which are neat and well kept. He also gives daily attention to his personal cleanliness and appearance.

11809

9. The custodian seeks new and better ways of doing his job, and when he finds them, he puts them into practice.

10. The custodian realizes that he sets an example for many children, and he strives to be worthy of their trust.

QUALIFICATIONS FOR CUSTODIANS

1. Character and Habits
2. Health
3. Intelligence
4. Age
5. Variety of Ability
6. Previous Experience
7. Appearance
8. Education (formal)
9. Pride (self-respect)
10. Marital Status
11. Citizenship
12. English Proficiency

Character and Habits. Good character traits are essential for a custodian. He must be the type of person with whom parents

11810

are willing to have their children associate. He should be dependable and always show courtesy. He should never use intoxicating liquors, drugs, or abusive language around students.

Health. A custodian should be given preference if he is vigorous, strong, alert, and healthy. There is a certain amount of carrying, lifting, and climbing that must be done in his duties. A previous health record can serve as a valuable guide. Good health is important. Most schools require an annual physical examination. The custodian must be free from contagious diseases and from any physical defect that would handicap him in his work. It should be pointed out, however, that many disabled people make excellent custodians.

Intelligence. A custodian must be able to think for himself. The demands of a modern school facility are tremendous.

Age. The minimum age limits normally preferred by those who employ custodians range from 21 to 25, and the maximum age limits from 45 to 50. While these are age

11811

$$I_{line} = I_{coil}$$

With delta connected windings

$$E_{line} = E_{coil}$$

$$I_{line} = 1.732I_{coil}$$

limits desired for new men, it should not have any influence on those already in positions because some of our most reliable custodians do not fall within these age limits.

Variety of Abilities. Because of the varied nature of a custodian's work, he must be able to do a multitude of things, and, hence, he must possess a diversity of skills. He should have some mechanical ability; he should be able to make minor plumbing repairs; he must have a knowledge of electrical work which will enable him to avoid such errors as overfusing; and often, he may be called upon to be a painter.

Previous Experience. Preference is usually given to a custodian who has had previous experience, other things being equal. Experience in a field related to custodial work is valuable if there has been no actual experience as a custodian.

Appearance. A custodian should be neat in his dress and personal appearance. When this is true he will usually take greater pride in his job. A distinctive uniform, consisting of shirt, trousers and tie will tend to enhance the importance of the position. Visitors and teachers will react more favorably

11812

toward the custodian and the school in general if he presents a neat appearance.

Education. It is desirable that a custodian have as much formal education as possible. Many schools give preference to those having at least an eighth grade education. If one has gone through high school he can better appreciate the problems of education and will probably be more cooperative toward the educational program.

Pride. Pride in one's personal appearance and job should be characteristic of a good custodian.

Married Status. In most cases, school personnel prefer a custodian who is married because they feel he is more reliable and more sympathetic to children.

Citizenship. He should be a citizen of the United States and an active resident of the community in which he is custodian. A local resident, as a rule, will take greater interest and pride in his work.

English Requirements. Because custodians have to read extensive directions and other written materials, he must be

11813

able to comprehend the English language. He must keep records and furnish reports; therefore, he must be able to read and write proficiently.

SAFETY AND HEALTH

The safety and health of the teachers, pupils, and personnel. Although this responsibility belongs to the administration, the necessary sanitation and care of the building falls within the job description of the custodian. He must keep close scrutiny over the optimum control of temperature and ventilation, as well as all factors of safety.

GENERAL SAFETY RULES

Know your fire extinguishers. The directions on every type of fire extinguisher in the building must be read, and now is always the best time to do it. It can potentially save the lives of many pupils. Know which extinguisher to use on various kinds of fires, especially electrical fires. People are often electrocuted by using the wrong extinguisher on an electrical fire. Extinguishers must be checked (recharged as needed) and tagged each year.

11814

Exit doors. Keep doors free of chains, locks, and other obstructions while students or visitors are in the building. Passageways must also be kept free of obstructions.

Heating and electrical equipment. Keep electrical and heating equipment in optimal working condition. The custodian can make many minor repairs himself but for those he cannot, he should promptly make a written request for maintenance assistance. (It is helpful to keep a carbon copy of such requests.)

Trash and debris. Dispose of trash and debris daily by burning it in an incinerator or by daily collection.

Catch-all. Don't let any area of the school become a catch-all for items of little or no value. Dispose of them.

Flammable liquids. Liquids such as gasoline, mineral spirits, lacquer thinner, paint thinner, turpentine, kerosene, and alcohol should not be stored in the school if it can be avoided. If it is absolutely necessary, they must be kept in safety cans stored in locked or ventilated storerooms, or in locked metal cabinets.

11815

Oily rags and dirty mop heads. Oily rags and dirty mop heads should be laundered regularly, or burned if they have no value. Oily rags and dirty mops to be laundered should be kept in air-tight metal cans.

SCHEDULE

In order to be functional any schedule must be flexible enough to allow for emergencies. A pre-arranged schedule is often disrupted by special programs or events, particularly around the holidays. Rainy weather, sickness, breakage of glass or equipment, vandalism to school property, special visits by the nurse, doctor, dentist and others often create special cleaning problems that must be given special attention and fitted into a functional schedule.

EPILOGUE

As one can readily see, the roles and responsibilities demanded of the modern-day custodian are many and varied. It is indeed false economy for any school administration to build a multimillion dollar building, and then expect to keep

11816

it functioning at an optimal level with cheap or minimal tools and equipment. It is equally false economy to believe that a school administration can hire a highly dependable custodian for minimum wages. Any discerning person, even with a minimum number of college courses in business and finance, can readily see the necessity for purchasing both qualitative and quantitative tools and materials for a well-paid custodial staff.

11817

CHAPTER II

GENERAL CLEANING

The old adage that an ounce of prevention is worth a pound of cure is the very essence of general cleaning. General cleaning brings the custodian into regular contact with practically every segment of the school plant and enables him to be fully aware of the conditions and needs of the entire building. Few, if any, custodians are truly effective unless they are systematic in their approach toward the total cleaning program. A Custodial Master Cleaning Schedule, which includes not only every cleaning task to be performed, but when it is to be performed, is not an easy task to develop. It usually requires deliberate study in a joint effort on the part of the custodian and school principal, and includes many trial-and-error approaches before it becomes totally satisfactory. The custodian must thoroughly understand the schedule and have a working knowledge of all the tools and materials necessary in carrying out the cleaning program.

Once the custodian has developed a reliable and workable cleaning schedule, which includes every cleaning task to be performed and when, he must then make sure that the schedule is

11818

adhered to at all times, and that the tools and materials necessary to do the job efficiently are kept in sound working condition. If the custodian is determined to see that these two things are well in hand, he is on his way to doing his job in an orderly and effective manner.

One of the most helpful aids to any well organized custodian is a custodian cart. These carts are relatively inexpensive, and in many cases are home made. Their use is invaluable in assisting the custodian in his daily cleaning chores. Carts may be used to store and to carry all the tools and materials that are normally required for daily cleaning. The custodian should make sure that the cart is properly equipped with everything that he will need in order to complete his daily cleaning tasks. This will keep him from having to return to the supply room for additional materials or supplies once he has started his regular cleaning duties.

General cleaning is a broad term that includes both immediate and long range cleaning tasks. Most cleaning tasks such as classroom cleaning are normally done each working day. However, some tasks are performed weekly, monthly, semi-annually, or annually. An important thing to remember is that no matter

11819

when or how often a cleaning task is performed, it should be placed on the Master Cleaning Schedule in order to insure proper attention and care. Cleaning tasks which are performed daily are commonly referred to as Daily Cleaning Operations, while the other tasks are called Other Cleaning Operations.

This chapter is divided into three general areas. The first deals with tools, equipment, and materials which are essential to good custodial care. The second recommends a time schedule for certain cleaning tasks and the order in which the tasks should be performed. The third section describes some of the better methods used by effective custodial staffs, and concludes with recommended precautions concerning the storage and handling of tools, equipment, and cleaning materials.

Although it is generally recognized that custodians have their own special way of doing certain cleaning tasks, it is hoped that they give serious consideration to the methods outlined in this chapter on cleaning. The suggestions and guides presented have been tried and proven by many knowledgeable custodial staffs across the country and should be of considerable assistance.

11820

The difference between being an average custodial staff or a superior one is often determined by whether or not a staff is open to new ideas and suggestions. This choice is yours!

TOOLS, EQUIPMENT AND MATERIALS

As indicated previously a custodial staff can be only as effective as the tools and materials that it has to work with. This is one of the major shortcomings in custodial services today. Millions of dollars are spent to construct a school building but frequently only a few hundred dollars are allotted for the tools and equipment to operate and maintain it. The custodial staff that has adequate materials and supplies is indeed fortunate.

The kinds of tools, equipment and materials which are necessary in maintaining a clean, functional school building are broken into two general categories. One is concerned with the necessary equipment and materials to carry out the day-by-day tasks and the other concentrated on the non-daily cleaning operations.

Daily cleaning operations frequently necessitate some kind of custodial cart which will hold the necessary cleaning

11821

With wye or delta connected winding

$$P_{coil} = E_{coil} I_{coil}$$

$$P_t = 3P_{coil}$$

$$P_t = 1.732 E_{line} I_{line}$$

(To convert to true power multiply by $\cos \theta$)

Resonance

At resonance

$$X_L = X_C$$

Resonant frequency

$$F_o = \frac{1}{2\pi\sqrt{LC}}$$

Tube Characteristics

Amplification factor

$$\mu = \frac{\Delta e_p}{\Delta e_g} \text{ (i_p constant)}$$

$$\mu = g_m r_p$$

A-c plate resistance

$$r_p = \frac{\Delta e_p}{\Delta i_p} \text{ (e_g constant)}$$

Grid-plate transconductance

$$g_m = \frac{\Delta i_p}{\Delta e_g} \text{ (e_p constant)}$$

Decibels

NOTE: Wherever the expression "log" appears without a subscript specifying the base, the logarithmic base is understood to be 10.

Power ratio

$$db = 10 \log \frac{P_2}{P_1}$$

Current and voltage ratio

$$db = 20 \log \frac{I_2 \sqrt{R_2}}{I_1 \sqrt{R_1}}$$

$$db = 20 \log \frac{E_2 \sqrt{R_1}}{E_1 \sqrt{R_2}}$$

NOTE: When R_1 and R_2 are equal they may be omitted from the formula. When reference level is one milliwatt

$$dbm = 10 \log \frac{P}{0.001} \text{ (when P is in watts)}$$

Synchronous Speed of Motor

$$r.p.m. = \frac{120 \times \text{frequency}}{\text{number of poles}}$$

1179

materials. These materials include, among other things, a portable vacuum cleaner that can be used for general dusting and vacuuming, a waste container lined with a disposable plastic liner, and a clip board with an attached maintenance memo pad. The following items also should be placed on the cart before the custodian starts on his regular classroom and general cleaning tour: treated dust mop with a 16" to 18" head on a swivel, a wet mop weighing about 20 ounces with a 60" handle, a 30" to 36" floor broom for the corridor, a 16" to 18" floor broom for classrooms (the corridor and classroom broom are often referred to as floor brushes and are pretreated before using them), dust pan, sponges, absorbent cloths, pretreated dust cloths, chamois cloths for chalkboard and windows, counter brushes, chalk and erasers (for exchanges), waste cans (for exchanges), buckets or pails for the cleaning solution and rinse water, and a general purpose detergent and a neutral cleaner in plastic spray bottles. The custodian cart should also have a small tool chest used for preventive maintenance and include such things as: chair glides, lubricant, pencil sharpener cutter replacements, putty knife, pliers, hammer, screwdrivers (regular and phillips head), wrench

11822

(adjustable), and a small amount of sandpaper, nails, and screws. The custodian should also make sure that he has the following equipment and materials for his non-daily cleaning operations: drop cloths, variety of mops and brooms, squeegee, ladders, mop wringers, extension cords, heavy duty cleaning solutions, neutral cleaning solutions for window cleaning, window covers, and other necessary materials.

It would be difficult to list all the tools, equipment, and materials that is required for any given custodial staff. The important thing is to make a comprehensive survey of the school cleaning problems and acquire those materials and supplies which will enable the custodian to do a superior job.

GENERAL CLEANING TASKS: ORDER AND SCHEDULE

This section outlines most of the cleaning tasks normally classified under General Cleaning. Recommendations are made describing the order in which these tasks should be performed.

DAILY CLEANING OPERATIONS

These include all cleaning chores which are normally performed each school day.

Classroom Cleaning. Classroom cleaning normally should

11823

never take place while class is in session. Most classrooms should be cleaned before or after school. In some instances, if classrooms are vacated near the end of the school day, they can be cleaned separately. However, classroom cleaning normally should be a total and distinct operation and nothing should interfere with the orderly process from the cleaning of the first classroom through the cleaning of the last one.

When cleaning classrooms, the custodian should park the custodian cart (which should be fully equipped for the total classroom cleaning task) outside the classroom door. Upon entering the individual classroom he should do the following: empty pencil sharpener shavings and wipe off cover and handle; look around the room and pick up large pieces of scrap paper and trash and empty these along with the waste basket contents into the waste container on the custodian cart, and then clean the waste basket if necessary. Next, the custodian should erase the chalkboard thoroughly and dry clean it. He should then clean or exchange the erasers and replenish the chalk supply, after having dusted or vacuumed the chalkboard tray and surrounding area. The custodian should then dust the entire room, including window areas, and furniture and equipment in the most

11824

time saving manner. When a vacuum cleaner is available, these areas should be vacuumed rather than dusted. Following the dusting the custodian should then do any necessary spot cleaning; such as removing soiled spots from the walls or furniture, or cleaning the sinks and other areas. He should then give attention to any minor preventative maintenance task, and write down any needed major tasks on his memo pad so that he can take care of them later. The custodian should then dust mop or vacuum the entire classroom, working toward the door. He should then empty the debris into the waste container located on the custodian cart. Following this he should straighten the furniture and equipment, adjust the window covers (while locking the windows), check the thermostat and adjust it if necessary, turn off the lights and lock up the room. The same procedures should be carried out in every classroom.

Other Areas. The library, gymnasium, cafeteria, work rooms, lounge, offices, and generally all other Daily Cleaning Areas follow the same procedures as outlined above. The trash or debris that is swept into the corridor is normally left as the last area to be swept and cleaned.

11825

Corridors. The walls, fire extinguishers and lockers should be vacuumed or dusted from top to bottom. Soil spots and other tasks such as water fountains should be cleaned, checked, and the faucets adjusted. The corridors should then be vacuumed or swept with a treated dust mop.

OTHER CLEANING OPERATIONS

The cleaning tasks described in this section do not normally require daily attention. Regardless of how often they are cleaned, they must be entered on the Master Cleaning Schedule in order to insure that they are systematically checked and attended to. Local conditions, such as the amount of dust, rain, vandalism, and quality of the physical plant have an import on these cleaning operations. The frequency of cleaning recommended in this section refers to average conditions and should not be construed as being absolute.

Chalkboards. Chalkboards should be thoroughly erased everyday. About once each week the chalkboard should be thoroughly dry cleaned. Wet cleaning (washing the chalkboard) should be avoided where possible and should never be wet cleaned over once a year as wet cleaning is harmful to the writing surface.

11826

Window Covers. Window shades and venetian blinds are the two most widely used window covers in school buildings. They both require dusting on an average of once a week, but may require a more thorough cleaning about twice a year. This is normally done during the Christmas holidays and during the summer months.

Windows. Windows normally require cleaning about as often as window covers and both should be cleaned at the same time. Because of rain, wind and snow, outside windows usually do not require a thorough cleaning more than once a year, but they should be cleaned as often as necessary. Thorough cleaning of windows should always be done each summer.

Light Fixtures. Light fixtures which are dirty are not only distasteful to the eye but greatly affect the learning environment of children by cutting down on the intensity of the light. They should be vacuumed or dusted several times a year and thoroughly cleaned twice a year. This cleaning task is usually tied in with the cleaning of windows and window shades and is normally done during the Christmas holidays and summer months.

Furniture and Equipment. Furniture and equipment should be vacuumed or dusted daily. During the summer months they

11827

should be moved into the corridor and checked over carefully for needed repairs and given a thorough cleaning.

Walls and Ceilings. Both of these areas should be vacuumed or dusted thoroughly at least once a month. Under normal conditions they are not cleaned more than once a year, usually during the summer months when the furniture and equipment have been moved to the corridor for cleaning.

PROCEDURES FOR INDIVIDUAL CLEANING TASKS

This section considers each individual cleaning task separately under General Cleaning, and discusses the procedures, tools, equipment, and materials necessary in accomplishing the task.

Pencil Sharpener. Each day the pencil sharpener should be wiped clean with a cloth or sponge dampened with a neutral cleaner. Occasionally, it may be necessary to squirt a drop of machine oil on the moving parts, replace the cutters, or install a completely new pencil sharpener.

Waste Basket. After emptying the waste basket it should be checked and cleaned (inside and outside) with a neutral cleanser. Old or unserviceable waste baskets should be replaced.

11828

as necessary without waiting for special requests.

Chalkboards, Chalk, and Erasers. The daily cleaning requirement for most chalkboards is normally satisfied by thoroughly erasing with a clean, dry eraser. About once a week however, many chalkboards, especially where teachers use them extensively (such as in math classes), require a more thorough cleaning. The dry cleaning method usually does an effective job. This involves erasing the board thoroughly with a good clean eraser, and then going over the chalkboard again with a dry chamois or similar cloth. In both of these cleaning methods the chalkboard will continue to appear chalky looking; this is as it should be. The third and final method, short of replacing the chalkboard with a new one, is referred to as the wet method. Generally, it is a good rule to apply the wet method only to slate chalkboards, and then only as the need demands it. Slate is a natural stone which has been quarried, ground, and polished into sheets of about one-half inch thickness. When the chalkboard fails to reflect or accept the writing of the chalk after being dry cleaned, it may be necessary to use the wet method. After the chalkboard has been erased and chamoised thoroughly,

11829

take an abrasive cloth and dampen it with clear warm water only and wash the chalkboard. After the board has dried thoroughly, completely chalk the entire board, just as would be done in breaking in a new board, and then erase the chalking. Rechalk the board a second time, from top to bottom and then from side to side, and then again erase thoroughly. The board should now be ready for use. Should some stubborn spots (ghosts) still remain, use a chemical such as pumice on a damp rag and attempt to remove the spots. If the color of the chalkboard appears on the cleaning rag then it is time to stop, as considerable damage may occur.

One of the best methods of keeping a chalkboard in good condition is to use the right kind of chalk. The best kind is usually white chalk made of limestone, composed of 95-97 per cent whiting, and only 3-5 per cent glueing or binding.

Erasers are equally important as chalk. A good felt eraser attached to a durable back is the most popular one on the market and is quite satisfactory. Another popular eraser is the rubber-leather combination which cleans with the aid of static electricity by attracting the chalk dust.

11830

Dusting. One of the most effective and best all around dusters on the market today is the portable vacuum cleaner. It can be used for practically every dusting task. It is lightweight, relatively inexpensive, and does an extremely thorough job when used with proper attachments. It can be used to clean erasers, vacuum chalkboard trays, walls, windows, window covers, furniture and equipment. A second but less effective dusting technique is to pretreat an abrasive cloth with a good neutral cleaning solution. The abrasiveness of the cloth tends to cut and hold the dust, while the cleaning solution serves to free stubborn dust or dirt loose from the surface. There are various kinds of dusters on the market today: glove type which can be worn over the hand securely, the back-pack portable vacuum cleaner which weighs less than ten pounds, and the mop duster which is used primarily to pick up dust from the floor.

Soiled Areas and Special Areas. Any area within the General Cleaning domain which requires special attention beyond dusting, such as soiled spots on walls or furniture, water fountains, sinks and other equipment are best cleaned by using an abrasive cloth or sponge and a neutral cleaning solution.

11831

Comparison of Units in Electric and Magnetic Circuits

	Electric circuit	Magnetic circuit
Force.	Volt, E, or e.m.f.	Gilberts, F, or m.m.f.
Flow	Ampere, I	Flux, Φ, in maxwells
Opposition.	Ohms, R	Reluctance, $\mathcal{R}$
Law.	Ohm's law, $I = \frac{E}{R}$	Rowland's law, $\Phi = \frac{F}{\mathcal{R}}$
Intensity of force	Volts per cm. of length.	$H = \frac{1.257IN}{L}$, gilberts per centimeter of length.
Density.	Current density—for example, amperes per cm^2.	Flux density—for example, lines per $cm.^2$, or gausses.

1180

After these areas have been cleaned they should be wiped dry with another clean cloth or sponge.

Window Covers. Venetian blinds are dusted best by turning the slats all one way and then vacuuming or dusting that side and then the other. Washable covers and venetian blinds are best cleaned with a sponge and neutral cleaning solution by removing the window covers from the walls and placing them on a clean flat surface. If the slat tapes are of non-shrinkable material, the entire blind can be cleaned thoroughly by placing it in a tank of water mixed with a neutral cleaning solution, and then removing it and placing it into another tank of clear rinsing water. Blinds should be allowed to dry thoroughly before rehanging.

Light Fixtures. Light fixtures can be effectively dusted with either a portable vacuum cleaner or a pretreated dust cloth. A more thorough cleaning job is accomplished by removing the light fixture covers and placing them in a tank of water mixed with a neutral cleaning solution, and then transferring them into another tank of clear warm rinse water. A sponge or abrasive cloth will serve to cut the dirt and a chamois or absorbant cloth should be used to dry the cover

11832

before replacement. The apparatus around the lights can also be wiped with a damp sponge or cloth that has been treated with a neutral cleaning solution. The cleaning of light fixtures is normally a two man operation. While one man is removing the covers and cleaning the lighting apparatus, the other man is on the floor cleaning the covers and rinsing them. This is also an ideal time to replace old bulbs.

Windows. The most widely used tools and materials in window cleaning are warm water, sponge, squeegee, and a good chamois. Occasionally, it may be necessary to add alcohol or ammonia to the water if the windows are extremely dirty. A good sponge can work on any part of the window area without damaging it and can get to difficult areas. The squeegee is an effective tool for removing the water from the window, but a good chamois can thoroughly dry and polish at the same time. However, the polishing of windows takes excessive time which could be better used to clean additional windows. Precautions should be taken to make sure drop cloths are placed at the base of the windows to catch excess water or drippings. Extension rods should be used to reach difficult outside windows.

11833

Furniture and Equipment. All furniture and equipment should be moved to the corridor (or similar area) for a thorough cleaning. This allows another cleaning crew to move inside the classroom and clean the windows, window covers, light fixtures, and ceiling and walls while the furniture and equipment are being cleaned. One important aspect of annual furniture cleaning is the maintenance task that can be performed at the same time. Gliders can be removed and replaced, new bolts or screws can be inserted, and rough places can be sanded and smoothed. Gum and other foreign materials should be removed from the underside of the furniture and equipment while the cleaning is taking place. A good sponge or abrasive cloth and a neutral cleaner are effective materials in cleaning furniture and equipment. Two buckets are required; one for the cleaning solution and the other for warm rinse water.

The furniture and equipment should be wiped dry after cleaning.

Wall and Ceiling Cleaning. Periodic dusting or vacuuming will help maintain the proper appearance of these two areas. Many walls and ceilings are not washable and

11834

special precaution should be taken to ascertain the type of material and paint used on these areas. Spots normally can be removed from acoustical ceilings with art gum or wall paper cleaner. Extremely soiled walls and ceilings are often less expensive to paint than to clean, and this cost factor should be highly considered. When washing these two areas a neutral cleaning solution will usually do the job, and can be applied either with a sponge or abrasive cloth. In some cases a brush might be necessary. Drop cloths should be placed around the work area, and the walls should be cleaned from the bottom up, and the ceilings from the corners inward. Areas three-to-four square feet should be cleaned at a time; and they should be rinsed off and dried before moving to the next three-to-four square foot area. Special precaution should be taken to see that there is no overlapping of areas at the borders, as this tends to highlight the overlapped areas. Special attention should also be given to drippings and streaks. Both should be removed immediately before they dry, as they too tend to show up after the wall has dried.

11835

Cleaning Solutions. A neutral cleaning solution will generally accomplish most cleaning tasks around the school without too much difficulty. Custodians should be fully aware of the chemical make-up of all the cleaning detergents and solutions which they use. Most of the neutral solutions have an ammonia, alcohol, tri-polyphosphate, or similar base. Chemical solutions with an unknown base should be avoided. When a custodian mixes his own cleaning detergent or solution he must follow the exact directions of the manufacturer.

11836

11837

STORAGE OF CUSTODIAL EQUIPMENT AND MATERIALS

A custodial storage room that is well organized and large enough to store all the materials, tools, and equipment is highly recommended. A large pegboard and plenty of shelf space are necessary. A running inventory of all materials, tools and equipment should be kept in an accessible place.

Shelf space adequate for the storage and rotation of paper goods, cleansers, small equipment and other supplies should be provided. Racks for brooms, mops and brushes are also needed. This aforementioned rotation should be done by marking the date each new shipment arrives and placing it behind existing materials and supplies, in order that the older materials are used first to avoid ageing and spoilage. The following recommends appropriate procedures for the storage and maintenance of tools and equipment:

Brushes (Floor). These brushes should have the head turned frequently to eliminate deforming. Hang the brushes with the bristle down. This will allow a wet brush to drip dry properly.

11838

Buckets. Each bucket should be marked or identified as to purpose, such as scrubbing, rinsing, or waxing, and should not be interchanged. Buckets should be rinsed and wiped dry after use to prevent rust and corrosion.

Carts. All custodian carts should be stored in a place that will not interfere with foot traffic or create a safety hazard.

Chamois (Chalkboard). These should be shaken out well after use, and stored in a place free from oil, grease, water, wax and other foreign materials.

Chamois (Window). These should be washed, rinsed and allowed to dry on a rack provided for this purpose, and not dried in the sun or next to a heating unit.

Cleaning Materials. All cleaning materials, other than flammable liquids, should be stored on shelves and clearly marked as to content.

Corn Brooms. Should be hung on suitable hangers with the bristle down but not touching the floor. Wet the bristles of a new broom prior to the first usage. When using the broom turn frequently to eliminate deforming.

11839

Counter Brushes. These brushes should be hung on hooks to allow them to retain their shape.

Dust Cloths. These should receive the same treatment as dust mops, and stored where they will not come in contact with other materials.

Ladders. Ladders should be kept in good repair and in a room away from the reach of children. Long ladders should be hung on pegs attached to the wall.

Liquids (Flammable). Alcohol, gasoline, paints, thinners, kerosene, and similar flammable materials which are kept in the school building should be stored in a metal fire proof cabinet. Where possible, these items should not be kept in the school building.

Mops (Dust). These mops should be treated with a non-oily treatment and stored in an air tight metal container for a 24-hour period prior to usage. Shake and fluff mops after using and place on hanger. Never clean mops by striking against a wall or other hard object. The mop heads should be changed, laundered and retreated once a week or as necessary.

11840

Mops (Wet). Each mop should have a hanger marked for its specific purpose, such as scrub, rinse, or wax. Each mop should then be rinsed, combed and fluffed before storing. These mops can be hung with the head either up or down but always hung, and never touching the floor.

Mop Wringers. Mop wringers should be rinsed and cleaned, and the strings and debris removed after each usage. They should then be placed on the mop buckets to dry.

Rags (Oily). These rags should be stored in an air tight metal container. When no longer serviceable, they should be destroyed by burning.

Rags (Wet). Wet rags should be rinsed and spread on a rack to dry in a well ventilated area. Do not hang over equipment.

Sponges. Sponges should be rinsed daily and placed on a rack to dry.

Squeegees. Wipe squeegees clean and hang so that the rubber blade will not touch other materials.

Vacuums. Vacuums should be kept in a storage room with the hose and other attachments on a pegboard or a storage board.

11841

CHAPTER III

RESTROOMS AND RELATED FACILITIES

No single area of the school plant reveals the quality of the custodial program more readily than does the restroom and shower area. The remainder of the school plant may demonstrate excellent custodial service, however, if the restrooms and showers are soiled and odorous, the total program may be severely critized. The general efficiency of the custodial staff is often judged by the maintenance of these areas.

Public health, public relations and professional pride demand that the restroom maintenance be of acceptable quality. The excellence of this service has educational implications for habits and attitudes of the pupils. It may be of a positive or negative influence on student behavior and thus offers an educational challenge to the custodial program of the school. Pupils tend to respect a clean orderly restroom, but have little regard for one that is soiled and untidy.

11842

PROBLEMS OF RESTROOM SANITATION

The greatest problems in maintaining restroom and shower sanitation are bad odors, poor lighting, and improper temperature.

Poor Ventilation. Bad odors are of two types: (1) the temporary odors that result from the process of removing waste materials from the body, and (2) permanent, lingering odors arising from unclean fixtures, urinal traps, urine stained floors, stained partitions and decayed organic compounds. The first type of temporary odor generally is quickly removed by an adequate exchange of fresh air, or ventilation. The serious type of odor, the permanent lingering type, is the result of unclean conditions, improper building materials, and improper care of the urinals and commodes. Four particular sources of bad odors are noted: (1) soiled toilet seats and stools, (2) soiled urinals and traps, (3) soiled and stained floors (especially concrete and terrazzo floors), and (4) soiled wainscot and certain partition materials.

Bad odor constitutes one of the main problems of restrooms and shower room sanitation. The two ways to

11843

eliminate this problem are (1) proper ventilation to remove polluted air, and (2) good cleanliness to remove the source of the odor.

The use of deodorants has been highly questioned. The purpose of a deodorant is to neutralize or offset the disagreeable effects of a bad odor. It is not, however, a disinfectant but merely substitutes one odor for another. In most cases, deodorant blocks or sprays are merely used to cover up a dirty restroom or shower room. Since clean restrooms and showers do not smell, deodorants (perfumes) are not needed or recommended.

Special attention should be paid to the ventilation of the shower room and adjoining dressing rooms. Lockers should be designed and located for maximum ventilation.

Poor Lighting. Poor lighting has been noted as another problem in restroom and shower area sanitation. Where there is poor illumination, the occupants tend to take less care of the facilities. Consequently, light bulbs should be cleaned or replaced when necessary. When painting, light colors should

11844

be chosen since light hues reflect more light. Epoxy paint in high use areas, such as restrooms, offers more protection and ease of maintenance than latex or enamel type paint.

Improper Temperature. Under certain temperature and air movement conditions, there is little exhaust action even when the windows are open. For example, on cold days the warm air within a building may tend to rise through open stairwells and create a suction action that will cause the outside air to be drawn in through the open toilet room window, driving the toilet room odors into the building corridors. If a custodian must depend on window ventilation, he should study the various conditions that will influence the ventilation and make proper adjustments.

Restroom odors become more noticeable as the temperature within the room rises. Consequently, the temperature should be maintained at an optimal level. While the noted desirable temperature for classroom areas is 70 to 75° Fahrenheit there is no reason why restroom temperatures should be that high. Children are not expected to remain in these rooms for any extended period, and loitering

11845

should be discouraged. A temperature of 67° Fahrenheit is not unhealthful for the limited time children must remain there and the odor conditions are vastly improved.

The temperature for the shower room and dressing rooms should be maintained at 70° to 75° Fahrenheit; keeping in mind that the heat from the showers will raise the temperature in the immediate shower area.

TOOLS, EQUIPMENT, MATERIALS AND SUPPLIES

Tools and Equipment	Number Needed
Buckets (10 quart size)	2
Sponge (cellulous)	1
Rags (clean)	2
Pot Brush	1
Putty Knife	1
Mirror (small handle type)	1
Rubber gloves (pair)	1
Plunger or plumber's friend	1

11847

PROCEDURES

RESTROOM CLEANING

Remove waste daily. Collect all loose debris and trash. Empty waste cans.

Check and refill dispensers. Towels, toilet paper, hand soap, sanitary napkins.

Sweep floor. Remove loose material and gum from floor.

Dust. Include all ledges, toilet partitions, and surfaces requiring dusting.

Clean fixtures and wash basin. First wet down the basin. Using the pot brush, and neutral cleaner solution, clean the basin inside, outside, and underneath. Be sure to wash surrounding wall area and piping under basin. Do not use an abrasive cleaner or acid cleaner on sinks. Rinse solution from basin. Wipe basin with a wet sponge of clear water. Wipe chrome with a paper towel. Inspect for maintenance needs as it is being washed.

Cleaning mirrors. Mirrors in the restroom should be cleaned with clear water and a clean cloth. After washing, the glass should be wiped dry with a chamois or paper

11848

towel, wiping vertically from top to bottom of mirror.

Cleaning urinals. The urinals and all adjacent areas should be cleaned at least once a day. Flush urinal and check water inlets and traps. Using a paper towel or pair of gloves, remove waste found in urinal. Using a neutral cleaner solution and a pot brush, wash outer surface of urinal and adjacent wall areas. Wash the urinal, including metal plumbing. Be sure to wash thoroughly the hidden under surfaces of the rim. Use the hand mirror to check cleanliness of hidden surfaces. Flush urinal and rinse the exterior with the sponge. Wipe the chrome with a dry rag or paper towel to polish.

Traps. Weekly, check and clean the urinal and floor traps. One cup of detergent solution may be left in traps overnight on occasion to combat odor and soil buildup in the trap.

Toilet cleaning. Flush the toilet and look for stoppage, clogging, and foreign objects. Use the plunger if needed. Force as much of the water over the trap as possible. Use the bowl brush and a rapid downward pumping action.

11849

A "plumber's friend" can be used to reduce the diluting of the cleaner, which will be added next. Proceed to each stool, repeating the same procedures. Return to the first stool. Using the small hand mirror, check the groove of the stool which is hidden from sight. If it shows a dark soiled stain or ring, use an acid bowl cleaner on the johnny mop or curved toilet brush and clean thoroughly. This is one source of permanent lingering odor. Don't allow the acid cleaner to splash on the exterior; if this occurs, wash it immediately with water. Flush toilet; while flushing, wash the acid cleaner from the underside of the rim. Rinse the bowl brush while flushing. Inspect under the rim or groove with a small hand mirror for cleanliness. Repeat the acid cleaner if soil is found. Wash the seat, hinge fittings, and exterior of the commode with neutral cleaner and pot brush. Wipe the areas with clean water and sponge. Wipe the chrome parts with a paper towel or dry rag for a polished effect.

Spot Cleaning. Remove finger prints, stains, and other markings from toilet partitions, doors, frames and walls

with the neutral detergent solution and wipe with clear water and sponge.

Maintenance check. Check all light fixtures and other mechanical equipment, such as ventilation, for cleanliness and proper working order.

Floors. Using the materials, equipment and procedures described in Chapter IV on floors, clean the floors daily.

SHOWER ROOM CLEANING

Inspection. Check and refill hand soap.

Dust. Include all ledges and horizontal surfaces in adjacent areas.

Clean fixtures. Include shower heads, soap dishes and adjacent wall and floor areas, using a neutral cleaning solution and pot brush. Rinse all ceramic tile in the shower area including walls, and ceilings, with warm water and hose. Wipe the fixtures with a dry cloth or paper towel.

Clean floors. See Chapter IV.

11851

171

CLEANING OF RESTROOMS

The recommended time for cleaning the restrooms is the late afternoon when most of the building occupants have left the school. Shower rooms should be cleaned after the last use of the showers in the afternoon.

Wash walls		x
Shower Room		
Clean shower heads and fixtures	x	
Clean walls	x	
Clean floors	x	
Dust	x	
Sweep appropriate areas	x	

11853

PRECAUTIONS

Special attention should be given to toilet facilities cleanliness because of the germ spreading factor found in unclean restrooms and shower rooms. Custodians should be careful to wash their hands after cleaning these areas before continuing cleaning operations in other parts of the building.

Special caution should be used when cleaning the toilet and metal shower dividers. Dividers should be dried thoroughly with special attention given to the ledges at the bottom.

11854

CHAPTER IV

CARE AND MAINTENANCE OF HARD FLOORS

Floors are the custodian's showcase. With the exception of the building exterior, probably no other area of the school plant portrays the quality of the custodial staff as conspicuously as the floors. The visitor sees the corridor floors immediately upon entering the school. His opinion of the entire school is at that time beginning to formulate.

If a good image is to be created with clean floors, the custodian will need to know floors and floor cleaning techniques. The quality of floor maintenance will improve as the custodian improves his knowledge and skill.

Common resilient floors include asphalt, asphalt tile, linoleum, rubber tile, vinyl, vinyl asbestos and cork. The physical characteristics of any flooring material always govern the methods of maintenance and the products which are chosen to properly treat and maintain it.

11855

TOOLS AND EQUIPMENT

Treated Dust Mops

Treated dust mops are the most important single item in the maintenance program of a school. The best types have swivel handles. Untreated dust mops are not recommended, as they merely stir up the dust, rather than pick it up.

Types of Dust Mops. The first expenditure for equipment should be treated, dry dust mops. One treated mop, size 16" to 18", will adequately dust five classrooms.

Care of Treated Mops. Treat the mops one day prior to using them. Mops 30" or wider should be used for corridor areas. Hang the mops in a head-down position overnight so that capillary action will move the treatment to the ends of the strands. Only a mop treatment solution that has been recommended by a reliable janitorial house should be used.

To clean the mop place it in an appropriate solution, and allow it to soak overnight. Then wash and rinse the mop in an old washing machine for four to five minutes, if possible. Untangle the snarls and hang the mop to dry before retreating it.

11856

Wet Mops

Each custodian needs a minimum of four wet type mops. These will be used as follows: one for scrubbing, one for rinsing, one for waxing, and one for sealing.

Types of Wet Mops. The best type of wet mop is a synthetic. Rayon is commonly used as it will normally last a little longer. Tests have indicated that it does a much better job, has the same absorbent factor as cotton, and will not streak or leave fibers as cotton mops often do. Several types of mops are available: flip top, spring type, big bulky type with wing nut (not recommended as it may rust rapidly), granny type with knot on top (rots quickly), and screw type.

The best weight in a wet mop is 20 ounce for most tasks such as mopping, sealing, and waxing. A male custodian normally requires a 60" handle, but a maid can better utilize a 54" handle on a 16 ounce mop. The 32 ounce mop is too large for anyone, and may create backache or twisted-spine problems.

Care of Wet Mops

Wet mops should be cared for in the same manner as

11857

dust mops. The cleaning process works equally well for both kinds.

Scrub Buckets

The best type is one with a 32 quart capacity. It should be on casters, and a wringer (push-down type) should be attached on the side. The wringer should accommodate a 20 ounce mop. Each custodian should have a minimum of two buckets because one should be used for mopping and the other for rinsing.

Push Brooms

Each custodian should have at least two push brooms. These should be the natural bristle type with a 16" - 18" head. These brooms are used mainly for restrooms and heavily littered areas.

Floor Machines

The larger the machine the easier it is to operate (up to a size of 23"). A 17" machine is designed to take care of approximately 10,000 square feet; a 20" machine will service 15,000 square feet; and the 23" machine will handle 20,000

square feet and over. A 23" machine can ordinarily do an area in half the time it requires a 17" machine to do.

Floor machines come in different weights and sizes, and the revolutions per minute will vary with weight and manufacturer. A floor machine should be wired for both 110 and 220-volt circuits so that it can be converted by merely flipping a switch.

The floor machine is designed to create friction. This implies that you need to know how much pressure per square inch is on the brush since this determines the machine's value. It should have approximately 2.3 pounds per square inch. If the motor is off-center, the machine will often be off-balance. The better kinds of machines are built low.

A stiff wire brush instead of a scrubbing or polishing brush should be purchased. Nylon pads can then be used on the brush for different jobs. Pads are designed for stripping, light scrubbing, buffing, combination, and high gloss. Three to four dozen pads can be purchased for the cost of only one scrubbing brush. Nylon also does a better job and lasts longer. The best way to economize on materials is to standardize.

A floor squeegee or wet/dry vacuum is helpful when using

11859

a floor machine. Wet/dry vacuums are rated by the amount of water sucked up per minute. The motor should be one to one and one-half horsepower.

Miscellaneous Tools

Some of the other tools which are desirable in the care and maintenance of hard floors are: counter brush, dust box, dust pan, putty knife, corn broom (for outside areas), and clean cloths (an ample supply). These tools should be carried in the custodian's cart, if one is available.

PROCEDURES

Sweeping Classroom Floors

If there is a secret to efficient room cleaning, it is -- BE SYSTEMATIC. Have the equipment and materials needed to do the job; have it organized to eliminate unnecessary steps and lost motion; and know how to use them. An inexperienced custodian may use as much as forty per cent of his time in needless and unproductive efforts to transport materials and equipment, i.e., looking for things, or trying to figure out what to do next.

4611 1183

In sweeping classroom floors a swivel-head treated dust mop (16 to 24 inches) should be used. Begin at the door and work around the edge of the room to the far corner. Work under and around the furniture, and push the dirt into the aisles without lifting the dust mop. Use a circular (figure eight) motion. After cleaning under a row of desks or chairs, mop the aisle, finishing up at the doorway entrance. When the dust mop becomes full with dirt and dust, push it through the door into the corridor, lift it a few inches and give it a sharp, quick shake. Do this far enough away from the corridor wall so that dust will not be deposited on the baseboard or door ledges. Pick up the dirt with the dust pan and floor brush and place it in the dust box. This should not be done directly in front of the door as a draft may scatter some of the dirt. One treated dust mop will normally sweep five classrooms adequately.

Sweeping Corridors

Place the tools at one end of the corridor away from the walls and woodwork. Take the floor brush and sweep the outer edges of the corridor (12-15 inches from the wall), insuring removal of dirt from corners, and under lockers. If the

11861

corridor is in use, the first round trip should be along the walls so that foot traffic will have a clean place to walk. Continue sweeping until the corridor is completely swept, shaking the dust out of the mop at the completion of each round trip. Each trip should overlap the previously swept strip by about four inches.

Sweeping Stairways

There are different types of stairs and treads that may require slightly different tools or procedures for sweeping. Most modern stairways can be swept with a treated sweeping mop. However, there are some stairs so constructed they may require the use of a floor brush. Stairs having square corners or rough, grooved treads are more difficult to sweep than stairs with rounded corners and smooth treads. A floor brush is the best tool to use on stairs of this description.

In sweeping stairs situated between two walls, the sweeping operation should begin at the bottom of the stairway. Sweep the dirt from one side toward the center of the tread on the way up. When the top of the stairway is reached, the dirt is then swept from the other side toward the center; then down to the

11862

next lower step, using a slight jerking motion in the corners. This procedure is continued downward to the foot of the stairs where the accumulated dirt can be picked up in the usual manner. This method can also be used on stairs having an open grill on one side and a wall on the other; but in this case, the side next to the grill should be swept on the way up. This method of sweeping allows traffic to use one side of the stairway while the other side is being swept.

When sweeping stairways situated between two rails, it is necessary to sweep from each side to the middle of the stair. This will keep the dirt away from the edge and prevent it from falling to the floor below. Stairs having a traffic rail in the middle sometimes offer an additional inconvenience for sweeping, but can usually be swept by the same method indicated above. Wide entrance stairs offer a different problem but are not too difficult to sweep unless the total width exceeds twelve to fourteen feet. The best method of sweeping is to sweep from the bottom on one side toward the top, taking about one-half the width of the stairs on the way up, and the other half on the way down. However, if the stairs are extremely wide, it

1863

may be necessary to sweep from the middle toward the edges all the way up, and bring the dirt down at the wall side of the stairs, making a trip to complete the opposite side.

Quietness is an important factor in the process of sweeping stairs, especially if done during school hours.

Sweeping Gymnasiums

Place the tools at one end of the gymnasium away from the walls and woodwork. If there is soil around the edges, take a floor brush and sweep the outer edges first, insuring removal of dirt from corners, and other confined areas. Begin at one end where it would be better to pick up the debris. Return trips should overlap previously swept strips by at least 4-6 inches. Continue sweeping in this manner until the gymnasium is completely covered, shaking the dust out of the mop at the completion of each round trip. Pick up the dirt, using the floor brush and the dust pan and deposit it in the dust box.

Mopping Floors

Damp Mopping. Sweep the floor first and remove any foreign matter sticking to the surfaces. Arrange movable

11864

furniture in a manner which will simplify the mopping. Dip one mop in the neutral solution and wring out slightly. Mop along the edge of the floor for a distance of about fifteen feet, coming no closer than six inches to the baseboard. Swing mop with a side-to-side (figure eight) motion until the entire floor area is covered. Dip a second mop in clean rinse water, wring out slightly and rinse floor, again using the figure eight motion for application. Redip the second mop in clean water and wring out thoroughly. Dry the floor as much as possible with this mop by repeated rinsing and wringing of the mop, covering the entire area.

Wet Mopping. This process is the same as damp mopping, except the mop head is saturated with cleaning solution in the beginning. It is then mopped onto the floor and allowed to remain for a short period of time in order to loosen the dirt. The solution is then removed with the mop and rinsed with clean hot water just as in the damp mopping process.

Scrubbing Resilient Floors

On new floors allow sufficient time for the tile to become tightly adhered to the floor before washing. The

1865

original scrubbing after installation should leave the floor absolutely free of any surface coating or foreign matter.

Utilizing a proper cleaning solution, use a floor machine to loosen dirt and old wax. Use a Number 2 steel wool pad or a nylon pad for stubborn dirt. Using a curved squeegee, push the water into an area where it can be picked up (either with a mop or a wet/dry vacuum). Use an 18" straight squeegee to pull the water into the pick-up pan (or use the wet/dry vacuum).

Rinse the floor with a fresh mop and clean water as each area is scrubbed. Do not overwet the floor or allow the water to stand. Change the rinse water often to insure a thorough job. Never mix the rinse mop with the scrubbing mop. Allow the floor ample time to dry.

Waxing Resilient Floors

Use a sheepskin applicator (for small areas only) or a clean rayon mop (for larger areas) to apply a thin coat of water emulsion wax. If necessary, apply a second coat after the first coat is thoroughly dry.

The wax used should contain no drying oils, no brittle

11866

shellacs, resins, paint ends or other quick-dry materials to hurry the natural process and cause the finish to be brittle. If possible, keep foot traffic off the floor for a few days to enhance the beauty of the floor. Color hues in the floor surface will be brought into high relief, and the floor should require no further waxing for several months, except in entrance ways.

In using the sheepskin applicator, a small open pan is needed for the wax. Both the floor and the applicator must be clean. Apply the wax in thin, even coats using smooth strokes. Taper the end of the stroke, and do not rub or brush in the wax. Allow to dry thoroughly before applying a second coat.

In using a rayon mop to apply the wax, the mop should first be soaked in water to soften it and wrung out dry. The 20 ounce size is ideal for waxing large areas. Place the liquid wax in a clean mop bucket with a wringer attached. Dip the mop into the wax and wring out about three-fourths dry. Apply the wax in thin coats. Avoid heavy waxing in order to prevent milky streaks. Allow the wax to dry overnight before polishing for maximum lustre.

11867

Sealing Resilient Floors

Make sure that the newly-laid floor is absolutely clean and dry, and that the surface is free of all foreign matter. Apply the undercoat seal in a thin, even coat with a sheepskin applicator or clean rayon mop to fill all pores and pits in the surface. To insure that the seal is thoroughly dry before waxing, allow it to cure overnight.

Care of Resilient Floors

When the condition of the floor warrants care (usually twice annually), scrub it with a light solution of neutral cleaner. After permitting it to dry, polish to a rich lustre.

The floor should be swept daily (see work schedule) with a treated dust mop. Frequently shake the mop to free clinging dust and dirt particles.

The wax finish should be periodically mopped with a neutral cleaning solution (see damp mopping instructions). This can then be followed by buffing instead of re-waxing in order to bring out the lustre of the floor. This eliminates frequent stripping of the wax.

After several months traffic you will want to patch in

11868

traffic lanes or heavily-used areas. Doorways and halls are examples of such areas. It is unnecessary to re-wax the entire surface because buffing will blend in the patched areas.

Twice annually (more often if necessary) the floor should be stripped by thorough scrubbing and re-waxing. Use a heavier solution of neutral cleaner than required for light mopping. Spread the solution onto the floor with a rayon mop and work the area well with a floor machine and a nylon scrubbing pad. After removing the solution, and rinsing well, allow the floor to dry completely before re-waxing.

Care of Terrazzo Floors

Follow the general directions for maintaining resilient floors. The only exception is in damp mopping. If all residue is carefully picked up, it is not necessary to rinse after mopping since the clean film of a cleaner actually enhances the lustre of the terrazzo. For white terrazzo scrub and mop with a solution which keeps the floors white.

Products for Terrazzo Maintenance

A neutral cleaner (free from acids, alkalis, metallic

11869

salts and damaging abrasives) should be used on terrazzo or any other types of hard flooring material. A special cleaner, formulated for white terrazzo and concrete, plus a whitening agent which prevents yellowing and preserves the original whiteness of the floor should be used.

A powdered cleaner which attracts and removes grease, oil, and soap film from Portland Terrazzo and other hard-surfaced floors is highly recommended. This cleaner has a bleaching effect on many non-removable stains.

Use a buffing type of terrazzo sealer that produces a tough, trackless, slip-resistant surface and never requires waxing. This type of sealer will not flake off or show traffic lanes. It brings to life the color hues that may have become dull and lifeless and aids in preventing efflorescence, bleeding bloom and dusting. Protection against penetration by water, dirt, and traffic wear is provided. It also makes daily dusting easier and eliminates frequent scrubbing.

A non-buffing type of sealer is a water emulsion, long wearing polymer coating. This seals and finishes porous surfaces with a color restoring beauty and protection. It is

1183 1184

easily applied, highly slip-resistant, repels soiling, and resists water spotting.

Use a non-buffing, penetrating, quick-dry sealer for terrazzo surfaces which are exposed to acids, oils, alcohol, grease and water. This type sealer is excellent for sealing old porous terrazzo and restores colors while resisting soiling and water spotting. This long-wearing surface facilitates cleaning and can be patched without recoating the entire floor.

Waxing floors				2-3 times

11872

What is a Neutral Cleaner?

We must refer to a technical scale of comparative values (see pH Table). Chemists use the term "pH" to express the relative alkalinity or acidity of a liquid.

Practically all detergents have a pH factor between 7 and 14. In other words most of them are alkaline. In a compound where the hands are exposed for any length of time, the pH should not exceed 10.5. Any greater amount of alkalinity can dry out the skin oils and cause irritation.

In the floor treatment industry the accepted "neutral cleaners" fall in a pH range of from 8 to 10. To better understand this, study the pH Table. For example, a pH of 9 is not just slightly more alkaline than a pH of 8, it is in fact 10 times more alkaline.

11873

pH TABLE

	Material	Approximate pH Value	Relative Acidity or Alkalinity in terms of Pure Water
		0	10,000,000
	1% Muriatic Acid	1	1,000,000
	1% Oxalic Acid	2	100,000
Acid	Vinegar	3	10,000
	Soft Drinks	4	1,000
	1% Boric Acid	5	100
	Cow's Milk	6	10
Neutral	Chemically Pure Water	7	1
	1% Sodium Bicarbonate	8	10
	1% Borax	9	100
	Neutral Liquid Soap	10	1,000
Alkaline	1% Ammonia	11	10,000
	1% Trisodium Phosphate	12	100,000
	1/2% Caustic Soda	13	1,000,000
	4% Caustic Soda	14	10,000,000

Advantages of Neutral Cleaners

Neutral cleaners can be used safely on any washable surface. They contain nothing injurious to floor surfaces and are effective in hard or soft water (hot or cold). Another advantage lies in its gentle, thorough cleaning ability. Whereas most cleaning products depend on one or two cleaning processes, a good neutral cleaner provides 100% cleansing action by combining many different processes.

The use of wetting action breaks the surface tension and gets the liquid directly on the contact surface. Penetrating action gets the solution down into the pores and crevices of the surface. The sudsing action attracts (pulls) dirt particles into the suds. The suspending action holds insoluble particles in suspension and does not allow solid particles to settle, which makes it easy to remove them from the surface. Emulsifying action breaks up fats and oils and mixes them into the water. It actually separates oil and makes it easier to remove. The dissolving action causes a breakdown of soluble materials which gravitate into the solution and reduces the cleaning time in half.

Just because the pH factor falls within the neutral range

11875

does not mean that the cleaner is safe. A cleaner which contains phosphates can form destructive crystals that often break up floor surfaces.

For the pH of some common substances refer to the preceding table (pH Table). When purchasing a neutral cleaner contact a reliable janitorial supply house.

PRECAUTIONS

General

In order to avoid soilage, do not place soiled tools against walls or furniture as this will cause the custodian extra work in keeping the building clean.

Wash, rinse, and dry all mops after each usage in order to prolong their life. An adequate supply of mops should be available to permit usage of a fresh mop each day. This allows proper time for cleaning and drying of all used mops.

Keep the sweeping mop clean and treated. After treating, the mop should be left overnight to allow the treatment to properly set. This prevents smearing the treatment on the floor.

11876

Do not shake mops near baseboards or furniture. This causes the dust to settle on these areas and adds to the work load of the custodian.

Make sure that all windows on the first floor (and in the basement) are securely locked. This is a general rule to discourage vandalism and break-ins.

Store sweeping mops (clean and treated) with the head down, preferably with the head in a metal box. This prevents the treatment from getting on the handle, and the metal box will prevent the treatment from rapid evaporation.

Sweeping Floors

Do not empty floor sweepings into paper containers, use a dust box. Paper containers have a tendency to allow dirt particles to "spill", whereas a dust box is specifically designed to hold floor sweepings until the custodian is ready to dispose of them.

Sweep corridors and gymnasiums in the direction in which they are laid out. By sweeping these types of floors in the prescribed manner, the custodian will pick up the dirt that normally gathers in the seams of these floors.

11877

Carry a counter brush to use in corners and under lockers. These areas are difficult to reach with brooms or mops, and the dirt and dust will gather if not removed regularly.

To erase streaking, run the sweeping mop over the floor where dirt has been picked up. If these streaks are allowed to remain, they will be ground into the floor and will require extra effort to remove them.

Mopping and Scrubbing Floors

When mopping, remove the cleaning solution thoroughly. If the solution remains on the floor, it may cause the floor to deteriorate rapidly.

When mopping immediately remove all water splashed on furniture and baseboards. This water may cause spotting and could lead to permanent damage.

Use a cleaning solution that is strong enough to clean, but mild enough to prevent stripping. If the solution is too weak, the custodian is wasting his effort. If the solution is too strong, the wax may be stripped from the floor and necessitate re-waxing.

Do not drag objects over a wet floor. This can cause

1878

streaking and may harm the wax or the floor. It may also cause permanent damage to the floor surface.

When scrubbing, do not attempt to scrub too much area at one time (limit to area approximately 4 ft. x 6 ft.). If too much area is covered, the solution will dry before it can be removed, and can permanently damage the floor.

Do not leave cleaning solution on the floor over five to eight minutes. The solution may penetrate the floor and cause permanent deterioration or a loosening of the binding materials in the floor.

When mopping and scrubbing avoid tracking of clean areas, and watch for slippery floor surfaces. Any areas which are tracked will need to be re-mopped or re-scrubbed. A wet floor is slick and can easily contribute to accidents.

Waxing Floors

When waxing floors a water-emulsion wax is superior to a spirit-solvent wax:

(1) water emulsion wax presents no fire hazard.

(2) water emulsion wax may be used on all types of flooring materials.

11879

(3) water emulsion wax does not require buffing to produce a good lustre.

(4) water emulsion wax is less slippery.

Use different mops and pails for each operation such as mopping, rinsing, sealing, and waxing. This technique will prolong mop life as well as insure that the floors will remain in sound condition.

The temperature of the rooms and the materials to be used should be above 70° Fahrenheit. This caution should be followed when sealing or waxing a floor.

Do not clean resilient floors with gasoline, turpentine, benezene or naphtha. These agents will soften and discolor the flooring materials. Soaps and cleaners containing fats, oils, alkali, or acids should never be used on asphalt or rubber tile.

Never use strong soaps or cleaners instead of a good neutral cleaner for proper floor care. Strong soaps are the frequent contributors of floor trouble and cause more damage than constant wear. Fading and discoloration can result and may actually cause the floor to slowly wash away.

Most strong soaps combine oil with a strong alkali such as lye. Alkali attacks the basic ingredients of most resilient floors, causing them to become brittle and hard and subject to easy chipping and cracking. The alkali may also cause a chemical change in color pigments and result in discoloration.

Do not use cleaning agents which are not readily soluble in water or strong detergents. These types of agents will dull the lustre and leave a white looking film.

Do not use varnishes, lacquers, shellacs or other plastic finishes on floors as these materials usually contain solvents that can permanently damage the flooring.

Sweeping compounds usually contain oil which is a fire hazard. Many of them also contain sand which is difficult to sweep and often will abrade if left on the floor.

The U. S. Bureau of Standards conducted a series of tests for several years which indicated that terrazzo floors were damaged when cleaners containing free alkalis, soda ash, and TSP)trisodium phosphate) were used on them. This damage occurred in the cement matrix where crystals formed from deposits of the cleaning agent and "exploded" the floor.

11881

Supervisors, administrators, and custodians should become fully cognizant of the many pitfalls and dangers of purchasing supplies and equipment from dubious janitorial supply firms. Secondly, each new or unfamiliar product, even from reputable firms should be given special caution and attention. Knowledgeable custodians will never guess at the amount of a product to use but will always abide by the manufacturer's directions.

11882

CHAPTER V

CARE AND MAINTENANCE OF CARPET

The use of carpet in schools has grown substantially in recent years. Carpet enhances the learning environment of a school. It aids in sound control, adds beauty, makes the school safer; and more importantly to the custodian, it cuts maintenance time.

The succinct fact that carpet cuts maintenance time does not mean that it is carefree. The most important aspect of carpet maintenance is daily care. A good program of daily care will maintain the appearance level of the carpet and lengthen the time between cleanings. A program of daily care insures that the sound control properties of the carpet are maintained, and the life of the carpet is prolonged.

To maintain carpet, an important factor for success is the availability and proper use of the correct tools, equipment, and materials. No procedure will work if the proper tools and supplies are not available. For proper carpet maintenance the custodian should be equipped with the following tools and equipment:

11883

Vacuum Cleaner. Proper selection of a vacuum cleaner is of utmost importance. A heavy duty commercial type, available from most manufacturers, is a must. This upright type of heavy duty vacuum is necessary for the large carpeted areas of a school. There are several important features which the school vacuum cleaner should include: (1) separate motors to drive the suction system, and the beater brush or turbulator, (2) a one-horsepower motor for suction, and at least a one-half horsepower motor for the beater brush, (3) a turbulator or beater brush, and (4) a heavy duty cord long enough to provide coverage of an area without excessive transferring of the plug.

Pile Brush. A machine which has two relatively stiff nylon brushes rotating toward each other serves two purposes: This type machine can be used for the dry powder method of maintaining carpet (which is discussed later). Such a machine also serves to brush up the face of the carpet where heavy traffic tends to mat down the pile.

Lightweight Vacuum. A lightweight vacuum (of the tank or back-pak variety) is most useful for sweeping under fixed furniture. A lightweight vacuum is also useful for cleaning

11884

in corners and along baseboards.

The following supplies are needed by the custodian in order to do an effective job of caring for carpet.

Dry Powder Cleaner. This material (which looks like fine sawdust) is the backbone of the supplies needed to take care of carpet. It is also used in maintaining larger areas of carpet, as well as serving as a valuable spotting material. This compound is chemically treated and must be stored in an airtight container to prevent evaporation of the chemical components.

Spotting Kit. The spotting kit should consist of a supply of dry powder cleaner and a small G. I. type brush. For stains which have an oily base, a petroleum solvent cleaning agent is needed. For water-soluble stains, which the dry powder will not absorb, a sudsing type detergent cleaner is effective. These solvents are available from most janitorial supply houses.

Clean Cloths. Only absorbent type cloths should be used in order to absorb as much of the liquid stain as possible.

385

To maintain both the life and appearance of carpeting, efficient vacuuming at established frequencies is an absolute must for any effective maintenance program.

The question of how often to vacuum carpeting depends to a great extent on the general layout of the building, the type of carpet, its color, traffic load, and type of outside soil commonly brought into the building. However, it is possible to classify the different areas of a building and use these classifications as a general rule for establishing the vacuuming frequencies that will assure satisfactory results for the care of the carpet.

Heavy Traffic Areas. These are the areas which receive the heaviest dirt loads and consequently should be vacuumed daily for maximum protection. These areas include entranceways, lobbies, regions around steps, first floor corridors and rooms, cafeterias, and other highly frequented areas. Not only should these areas be vacuumed daily, but in some instances (such as during periods of bad weather) a second or even third daily vacuuming is often necessary.

11886

Medium Traffic Areas. Medium traffic areas (because of their location) are normally subject to lighter dirt loads. By the time people reach these areas, most of the dirt brought in on shoes has been deposited in the heavy traffic areas. These medium traffic areas are generally on the upper floors of a building, or in rooms which are far removed from entrance-ways. Depending again on the type and volume of traffic, color of the carpeting and nature of the native soil, normally three vacuumings a week are usually sufficient to keep these areas clean and protected against wear.

Light Traffic Areas. Light traffic areas are the ones which have little or no spillage, and are usually so far removed from entrances that very little dirt is deposited there. These areas should be vacuumed as needed, usually not more than once or twice a week.

As the custodian vacuums, there are some important things to remember: A steady movement of the vacuum is better than quick jerky movements, since the vacuum must have time to work. The beater brush must have time to separate the pile, and the suction must have time to get the

11887

dirt out. With the proper type of vacuum cleaner only one smooth steady pass is usually required to do a thorough job of cleaning. Occasionally, the custodian should re-arrange the placement of the furniture in order to change the walk-way patterns and prevent one area of the carpet from receiving excessive wear.

SPOTTING

Before discussing spotting methods, it is necessary to become familiar with several types of stains which will most likely be encountered in a school building. These stains are generally placed into four categories:

Dry Stains. This type of stain is defined as loose stains. These are stains which do not adhere stubbornly to carpet fibers and normally can be removed by merely vacuuming. Stains in this category include sand, grit, cigarette butts, cigar ashes, and other types of non-oily and non-sticky stains.

Water Soluble Stains. These stains include sweets, starches, mud, and non-greasy food stuffs. Water soluble stains adhere to carpet fibers and do not normally respond

11888

to just vacuuming. These stains can be removed with water soluble based chemicals, such as the foaming type of detergent cleaners.

Petroleum Soluble Stains. These stains include grease, salad oils, tars, asphalt, shoe polishes and waxes. These may originate from spillage, an excess of oil laden dust in the air, or may be tracked in from the outdoors. These types of stains adhere stubbornly to the carpet fibers and can be removed with petroleum solvent chemicals.

Other Stains. These stains usually result from spillage or similar accidents. Such stains include a wide variety of substances such as alcohol, coffee, tea, soft drinks, blood, urine, fruits and juices, ink, paint, and a variety of other liquids. Depending on the nature of the stain, the stain remover will vary.

The first thing to do when a stain is discovered is to remove (immediately) the excess staining material. If it is a solid material then a putty knife may have to be used to scrape up the loose staining material. Always work toward the center of the stain to avoid spreading the staining material.

11889

If the stain is a liquid, an absorbent cloth or paper towel should first be used to blot up the excess liquid.

For non-oily liquids and dry stains, the dry powder cleaner method is an effective spot remover. In using the dry powder, first absorb the excess stain, then rub a hand full of powder into the stain with a small stiff bristled brush. Allow the powder to dry at least 30 minutes (longer, if possible) and then vacuum.

For stains which do not respond to the above treatment and which are non-oily, it may be necessary to use a foaming detergent type spot remover. Use the cleaner according to the directions of the manufacturer. Most of these cleaners are diluted with water. A sponge can be used to work the solution into suds. The suds are then applied to the spot with the sponge and rubbed toward the middle to keep from spreading the spillage. It is important to use only the suds and not the liquid, as excess moisture can damage the carpet. After the suds have evaporated, the spot should then be blotted to absorb any excess moisture.

If the stain is of the oily type, a petroleum solvent cleaning agent is needed. First, wipe up as much of the excess

spillage as possible by using a clean absorbent cloth (wipe from the outer edges of the spot toward the center). Then apply a small amount of the petroleum solvent cleaner to the spot and wipe with a clean cloth, again working from the outer edge to the center of the stain. Repeat the process until clean. If the spot is difficult to remove, and it is necessary to apply an excess amount of the solvent, it is recommended that a pad of absorbent cloth be applied over the spot, weighted down and left overnight to dry. This will help the spot to dry quicker and lessen the danger of the solvent attacking the latex compound on the backing of the carpet.

CLEANING

Even with a properly carried out maintenance program it will be necessary to thoroughly clean the carpet on occasion. The dry powder method of cleaning is highly recommended. This method is considered safe because it eliminates the use of moisture which may damage the carpet. Second, dry cleaning does not require skilled operators, and

11891

it has the advantage of allowing immediate use of the cleaned area.

To use the dry powder method of cleaning, the first step is to remove all loose furniture from the room. Sprinkle the powder over an area of about 10' by 10'. The powder should be used in the amount stated by the manufacturer. The next step is to apply the motor driven pile brush on the powdered area. Push the pile brush machine first in one direction, and then reverse and brush at a 90 degree angle across the first direction. Allow the powder to remain on the carpet until the chemicals have evaporated or until the odor is no longer present. Then vacuum the area thoroughly (any stray powder left on the carpet can be removed in subsequent vacuumings). A lightweight vacuum should be used to remove the powder close to the baseboard, in doorways, under radiators, and in other difficult places.

When the dry powder method of cleaning is no longer effective in maintaining the appearance level of the carpet, it may then be necessary to clean the carpet with some other method which employs liquid in the cleaning process. It is

11892

recommended that an outside contract be given to a company which employs and specializes in the steam cleaning method. This method is recommended because it does an efficient cleaning job and leaves very little moisture in the carpet.

11893

SUGGESTED TIME SCHEDULE

Cleaning Task	Daily	Every Other Day	Twice Weekly	As Needed
Spotting	x			
Vacuuming Heavy Traffic Areas	x			
Vacuuming Medium Traffic Areas		x		
Light Traffic Areas			x	
Cleaning (Dry method)				x(a)*
Cleaning (Wet method)				x(b)
Pile Brushing Walkways				x(c)

*(a) Approximately every 30 days for heavy traffic areas, 45-60 days for other walkways, and every 90-180 days for other areas.

*(b) Once a year maximum.

*(c) Heavy traffic walkways every 30 days. Medium traffic walkways every 45 days.

11894

CHAPTER VI

THE THERMAL ENVIRONMENT

Recent developments in school planning have revolutionized temperature management in school plants. Heating, ventilating, and air conditioning systems have literally changed the classroom environment. A successful custodian can no longer be considered merely the clean-up man. He must be a well-trained technician in many fields. The area of operation and maintenance of the heating and cooling facilities is among the most expensive part of school plant maintenance cost. No single problem is more controversial than proper room temperature. Since optimum temperature varies with different kinds of activities, it is imperative that the successful custodian ascertain as quickly as possible the proper temperature for each teaching area. A desirable temperature level for each kind of teaching space is included herein as a suggested guide.

The custodian should know the optimum temperature range for his building. There are conditions, however, over which he has very little control unless the school administrator is

11895

thoroughly aware of the principles involving heating and cooling problems. The most frequent thermal problem in a school building is overheating; and the person who contacts the custodian most often on heating matters is usually the classroom teacher. It is an established medical fact that the rate of body heat decreases as age increases, therefore, the older teacher is inclined to request for more heat than is actually healthful for her students.

DESIRED TEMPERATURES FOR VARIOUS AREAS

Area	Temperature	Overnight Temperature
Classrooms	70-75°	55°
Offices	70-75°	55°
Assembly Hall (when used)	68-70°	55°
Industrial Arts Shop	65-68°	55°
Corridors	65-68°	55°
Gymnasiums	60-65°	55°
Toilets	60-65°	55°
Bathroom and shower room	75-80°	55°
Swimming pools	75-80°	55°
Open Air Rooms	60-64°	55°
Kindergarten	72-76°	55°

11896

AIR CONDITIONING

Air conditioning systems for schools are used to provide a comfortable and healthful learning environment. Most of these air conditioning units are provided with individual room controls. Various units such as roof vents, grill covers, motors, fans, air filters, and controls require special attention of the custodian, and each component requires periodic inspection by specialists.

Care of Filters. Dirty filters contribute to inefficient and faulty performance of air conditioning systems. Periodic inspection is necessary to determine when filters should be replaced or advanced.

Lubrication. The manufacturer's instructions must be followed since requirements vary from unit to unit.

Seasonal Maintenance. General inspection, maintenance, cleaning, and repairing should be done as required. Periodic inspection must be made to assure proper functioning of belts, blowers, fans, linkages, and dampers.

11897

VENTILATION

A principle of proper ventilation is to produce adequate air movement within the classroom, while not creating undesirable air-drafts. The ventilation system should also displace foul air in the classroom and bring in a sufficient amount of fresh air from the outside to satisfy the needs of the occupants.

Systems. There are several types of ventilation systems which can be classified under the heading of gravity systems. The gravity system depends on the differences in the weight of hot and cold air for the air-movement. This system is economical to install and has good results under certain conditions. A modified system is one in which the gravity system principle is used, but which is accelerated by the use of radiators in the ventilating stacks, or by the use of small fans at certain intervals.

The mechanical system is one in which the air movement is controlled by fans which remove the air from the building. The mechanical system appears to be very efficient if properly installed and maintained.

11898

Ducts. Another method of ventilation is to provide ventilator ducts for each room from the building roof. Many of these ducts are installed in the cloakroom closet, while some are installed in the lower part of the wall in the classrooms. When ducts are used each room should be provided with a separate duct. The ducts should also be fire resistive to restrain the spread of fire from one part of the building to another.

Corridor Ventilation. Under this method, the stale air is taken out of the classroom through the door or through louvers and grills in the lower part of the door and deposited in the corridors. The air then circulates through the corridors and is removed from the building via the roof. This type of system is relatively inexpensive and has proven satisfactory for many buildings. Ventilation ducts should be equipped with dampers that can be opened or closed, however, they should not be kept closed during the school day. The closing of dampers during the day can prevent obtaining the desired amount of air required for proper circulation.

Unit Ventilator. Another type of ventilation system is

the unit ventilator. This type unit is normally installed in the classroom on the outside wall to provide both necessary heat, and proper ventilation. The entire operation of the unit ventilator is automatically controlled by a thermostat located on the inside wall of the classroom. This type of ventilation is essential in many areas since gravity ventilation is seldom satisfactory for toilets and locker rooms.

HEATING

A proper heating system is vital to a school. Detailed instructions on the appropriate care and operation of the heating equipment are equally essential. In maintaining high operating efficiency, the custodian must know how to intelligently operate and maintain the heating equipment and accessories. Neglect of the heating system will result in unnecessary repairs, increased fuel bills, and decreased heating efficiency.

Boilers are usually classified as low pressure or high pressure ones. Most school boilers are of the low pressure type. But, improper operation, neglect of valves and controls,

and general dirty conditions can make the low pressure boiler a potentially high pressure problem. High pressure boiler usage is decreasing in schools. Custodians should not attempt to use them unless they are thoroughly qualified.

Gauges should be checked out and tested while under pressure during the working season. Safety devices should be inspected during the down season and replaced as needed. Steam pressure and water level should be checked continuously while in operation. All electrical controls should be checked periodically by a competent electrician and kept clean at all times. In case of a low water problem in the boiler, the fuel and air supply should be stopped and the boiler allowed to cool. A thorough inspection should be made for cracks and other damage before reusing.

General Maintenance. The boiler and boiler room should be continually kept clean. Dirty boilers demand more fuel. Boiler flues should be cleaned thoroughly with wire brush as often as needed. Boiler water can be kept clean by using the blow down method when necessary. The boiler should be periodically inspected during the down season and repaired as needed. Sludge should be removed from oil tanks annually.

DESCRIPTORS - *UNITS OF STUDY (SUBJECT FIELDS); *AGRICULTURAL EDUCATION; SKILLS; *CALCULATION; MEASUREMENT; SLOW LEARNERS

ABSTRACT - This unit of study, designed for students lacking satisfactory computational and quantification skills, was prepared by the Department of Vocational Education, University of Kentucky. To develop ability to measure, weigh, and calculate agricultural units, the unit is organized into these competency areas: (1) determining length, (2) calculating area, (3) determining weight, (4) calculating volume, and (5) calculating cubic area. Each competency area contains a suggested teaching outline, learning activities, references and instructional materials. A bibliography is included. (FM)

AGRICULTURAL MECHANICS

UNIT: AGRICULTURAL WEIGHTS AND MEASUREMENTS

Major Teaching Objective

To develop in students the effective ability to measure, weigh, and calculate units of common agricultural products, structures, and resources

Suggested Learnings (Competencies) To Be Developed

1. To determine length
2. To calculate area
3. To determine weight
4. To calculate volume
5. To calculate cubic area

Prepared by
Billy J. Vice
Department of Vocational Education
College of Education
University of Kentucky

Disseminated by

11903

AGRICULTURAL MECHANICS

UNIT: AGRICULTURAL WEIGHTS AND MEASUREMENTS

Suggested Teaching Time

Number of class periods for group teaching:

In classroom, at school . . . . . _____
Outside classroom, at school . . . . . _____
Field trip (away from school) . . . . . _____

Total . . . . . _____

Place of the Unit in the Course of Study

This unit should be used with students lacking satisfactory computational and quantification skills. Students having disadvantages and learning problems often need to improve competencies similar to those suggested in this unit. Many of these mathematical skills are essential to satisfactory performance on the job, both during the time they gain occupational experience and after entering the job.

These learnings should be taught as more than a classroom session in mathematics. Actual structures, products, resources, and other items should be measured and quantified. Only those illustrations most appropriate for your students should be used in teaching. All of the examples listed should not be used, but generalizations can be made to these and to many more situations. Perhaps many of these learnings can be integrated into other units and this would allow teaching these learnings as part of a more comprehensive objective.

Suggestions for Introducing the Unit

Perhaps the best way to introduce this unit with students having academic disadvantages is a field trip to various situations where use of mathematics is needed in order to successfully carry out a job. Also, have students list computational problems they have experienced. Get them to understand the necessity of basic skills necessary to be successful individuals.

Have students experience real and common problems in order for all to feel the need for striving to improve their mathematical skills. Introduce mathematical concepts as needed to solve problems, but use the community as a classroom. Many situations at school can be planned to show students their needs and the use of mathematics.

11904

Suggested Teaching-Learning Activities

a. Suggested demonstration: How To Measure Length
b. Obtain objects to measure, proper measuring tools, and adequate materials for students to apply the skill after the demonstration by the teacher.

Suggested References and Instructional Materials

References

Vocational Agriculture Notebook, p. 6
The Farm Shop, pp. 215-222
Shopwork on the Farm, pp. 43-44
Metalwork Technology and Practice, pp. 435-436

2. To calculate area (square measure)

Area is the surface included within a given boundary -- a two dimensional concept. Examples of areas that might be measured for demonstrations include the following.

a. Acres of land within a boundary
b. Squares of building materials (roofing, greenhouse plastic, etc.)
c. Housing space for livestock

Tools for measuring area

a. Linear measurement tools are used to determine length of boundaries needed to calculate area (see the previous learning).
b. Calculating area involves linear measures and mathematical manipulations to determine the number of units.
c. Tools to measure length

Relationships of various square measures

a. One acre equals 10 square chains (10 chains x 1 chain).
b. Ten chains squared (10 chains x 10 chains) equal 10 acres.
c. One square mile ($5,280^2$) equals 640 acres.
d. One "square" of materials equals 100 square feet (10 feet x 10 feet).

Measuring land

a. Measuring land is really measuring area, but "sides" of the area must be determined. Two basic shapes of areas bounded with straight lines are rectangular and triangular land plots.

11906

-- Rectangular shapes

1. Determine length in chains (average length of the two longest sides).
2. Determine width in chains (average length of the other two sides).
3. See learning on measuring length.

-- Triangular shapes

1. Determine length of altitude; altitude is distance from one corner of triangular area to the point on base line that allows the line measured to be perpendicular to the base.
2. Take one-half of base line -- the line the altitude measurement perpendicular to.
3. See learning on measuring length.

-- Draw the shape of area measured and record the length on the paper.
-- Various ways the number of chains can be determined (pegs, marking with foot, counting, etc.)

b. Calculating area or square measure

-- Rectangular areas (and squares)

1. Determine length and width in chains (average two opposing sides) of boundaries.
2. Multiply average length of area in chains by average width in chains and divide by ten (point off one extra place to the left).
3. For example, an area 10 chains long and 1 chain wide contains 1 acre.

-- Triangular areas

1. Determine altitude (the distance of the line perpendicular to the base) and the length of the base in chains; the altitude becomes a side of a right angle.
2. Multiple length of altitude in chains by one-half the base line of the area and divide by ten.
3. For example, a triangular area with an altitude of ten chains and a base of two chains contains 1 acre.

Other measurements

a. Other surfaces and objects

-- Row feet per acre for crops (plants per acre)
-- Taking a sample of yield (portion of acre)
-- Capacity of machines at a certain rate of speed
-- Floor space of a building
-- Roofing materials required

11906

11907

-- Calibrate planting rates of machines
-- Determine amount of inputs needed (fertilizer, lime, pipes, tile, seed, paint)

b. The number of feet of row crops in an acre

-- Determine the average distance (in feet) between rows.
-- Divide the number of square feet in one acre (43,560) by the distance between rows in feet. For example, 30 inch rows, 2.5 feet wide, have 17,424 feet of rows per acre.

Suggested Teaching-Learning Activities

a. Suggested demonstration: How To Calculate Area
b. Find a real problem for students and have them apply the results of their calculations to the situation. Have them discuss the importance of the right answer and the need for mathematics in determining the solution.

Suggested References and Instructional Materials

References

Vocational Agriculture Notebook, pp. 6-7
Farm Management, pp. 428, 432

3. To determine weight

Weight is a numerical way of expressing the relative heaviness of an object. Some examples of important weights to obtain are as follows:

a. Yield per acre of crops
b. Livestock production (gain, pounds per head, etc.)
c. Ingredients, feeds, seeds
d. Amount of actual product in mixture or compound

Times when weight of products might be determined

a. Harvesting period (crops)
b. Selling dates (livestock)
c. Mixing ingredients and application of inputs
d. Inventory of stored products (seeds, feeds, fertilizers, etc.)

Some tools for measuring weight of objects

a. Scales
b. Unit weight (bushels, bales, loads)

Relationship of various weights

a. One ton equals 2,000 pounds.

eoeff

11908

b. One pound equals 16 ounces.
c. One pound equals 454 (453.6) grams.
d. One bushel equals the following number of pounds of seeds (only to be used as a source of information).

Pounds	Crops
-- 68-70	Corn, Ear (husked)
-- 60	Alfalfa
-- 60	Clovers
-- 60	Potatoes, Irish
-- 60	Wheat
-- 60	Soybeans
-- 60	Vetch
-- 50-60	Grain Sorghums
-- 56	Corn, Shelled (grain)
-- 56	Rye
-- 55	Potatoes, Sweet
-- 48-50	Millet
-- 48	Barley
-- 45	Timothy
-- 32-40	Sudan Grass
-- 32	Oats
-- 25	Lespedeza
-- 14-40	Redtop
-- 14	Other Grasses

Percentages or ratios (parts)

a. One percent is one part of a hundred -- 1/100 or 0.01
b. The many ways to write a percent (1%)
c. Examples of calculations involving percents

-- Pounds of TDN and digestible protein in a ration
-- Calculating interest rates
-- Pounds of pure elements in a given amount of fertilizer
-- Number of pure seeds and number that will germinate
-- Mixing parts into a whole with given consistency (supplement to add to grains, insecticides to mix with water, etc.)

Suggested Teaching-Learning Activities

a. Suggested demonstration: How To Determine Weight
b. Obtain weighing instruments and find some problematic situations for students to apply the skills needed in weighing various objects.

11908

11909

AVERAGE WEIGHT OF GRAINS AND FEED INGREDIENTS

4. To calculate volume of stored grains and roughages

Volume and cubic space are similar. However, the amount stored in the space often becomes the critical problem, and volume is usually converted to weight.

Problems of calculating volume:

a. The cubic space (or volume) must be calculated.

-- Cubic space is gotten by measuring and multiplying the length, width, and average depth (all usually in feet) of the structure or amount stored. The radius (one-half the inside diameter) and height must be determined for cylindrical structure.
-- For example, the cubic feet of grain in a rectangular bin that is 20 feet long, 8 feet wide, and 7 feet deep equals 1,120 cubic feet.

b. Cubic space or volume must be converted to units of measurement.

-- Divide the total cubic feet by the number of cubic feet for each unit of the type of product being calculated.

01811

11911

1.	Corn (grain)	1.25 cubic feet per bushel
2.	Corn (ear)	2.50 cubic feet per bushel
3.	Silage, high silos	*Approximately 40 cubic ft. per ton
4.	Silage, shallow silo	*Approximately 67 cubic ft. per ton
5.	Concentrates	*Approximately 45 cubic ft. per ton
6.	Hay, baled tight	*Approximately 100 cubic ft. per ton
7.	Hay, baled loose	*Approximately 133 cubic ft. per ton
8.	Baled straw	*Approximately 167 cubic ft. per ton

*Bulky materials vary in weight because of leafiness, moisture content, degree of packing, maturity, and type of crops.

-- For example, 1,120 cubic feet of capacity with 1.25 cubic feet per unit equals 896 units.

c. Formula for calculating volume of cylinders such as a silo, tanks, and the like

-- $V = \pi r^2 h$ (or $V = \pi d^2 h/4$)
-- $\pi = 3.1416$
-- Meanings of other symbols

1. Radius
2. Diameter
3. Height

Suggested Teaching-Learning Activities

a. Suggested demonstration: How To Calculate Volume
b. Measure and calculate the capacity of storage structures for grain and roughages. Also determine the actual amount stored in different shaped structures and with different products.

11913

Cubic measures include three-dimensional objects. Examples of cubic structures include the following:

a. Cube
b. Cylinder
c. Cone
d. Pyramid
e. Rectangular prism
f. Sphere

Examples of typical measures of cubic area

a. Storage structures

-- Amount of materials (feed, seed, fertilizers, etc.) stored in a given space
-- Storage capacity of barns, bins, silos, and the like

b. Building materials

-- Board feet of lumber
-- Cubic yards of concrete
-- Cement, sand, and gravel to mix one cubic yard of concrete

c. Ponds, water requirements, and liquid measures

-- Measurements

1. One gallon of water weighs approximately 8 pounds 5 ounces.
2. One cubic foot of water contains about 7.5 gallons.
3. One gallon equals 231 cubic inches.

-- Computing capacity of oblong tanks

1. To figure capacity in cubic feet -- length times width times depth, then this figure (product) minus the width squared times depth times .2146
2. To figure capacity in gallons, capacity in cubic feet times 7.5

-- Computing capacity of round tanks

1. To figure capacity in cubic feet -- radius squared times depth times 3.1416
2. To figure capacity in gallons -- capacity in cubic feet times 7.5
3. Stock tank capacity, height of 2 feet -- round type

11914

Diameter (In Feet)	Capacity (In Gallons)
3	100
3.5	140
4.0	185
4.5	235
5.0	290
5.5	350
6.0	420
6.5	495
7.0	570
7.5	660
8.0	750
9.0	950
10.0	1,170

(4) Stock tank capacity, 2 feet -- round end type

Width (In Feet)	Length (In Feet)	Capacity (In Gallons)
2	4	95
2	5	120
2	6	140
2	7	185
2	8	195
2	10	250
3	5	175
3	6	220
3	7	260
3	8	300
3	10	385
3	12	475
3	14	560

Lumber

a. One board foot of lumber is 1 square foot and one inch thick, or its equivalent.

b. Examples of boards containing 1 board foot:

-- 2" x 6" x 1' long
-- 1" x 6" x 2' long
-- 2" x 4" x 1.5' long
-- 1" x 4" x 3' long

c. Formula for figuring board feet

$$\text{No. of boards} \times \text{thickness in inches} \times \text{width in inches} \times \frac{\text{length in feet}}{12 \text{ (when length is in feet)}}$$

11914

11915

-- Example, 3 boards 2" x 4" x 10' = $\frac{3 \times 2 \times 4 \times 10}{12} = \frac{240}{12} =$

20 board feet

Concrete

a. Order of numbers for mixture is cement, sand, and gravel. By volume, a 1:2:3 mixture means 1 part cement, 2 parts sand, and 3 parts gravel.
b. Each cubic yard of mixed cement requires about 1.6 times as much unmixed cement, sand, and gravel. For example, one cubic yard (27 cubic feet) of cement requires about 43 cubic feet of unmixed cement, sand, and gravel.
c. If a wall is to be built that is 1 foot thick, 60 feet long, and 5 feet high, 300 cubic feet (or over 11 cubic yards) of concrete are needed.

-- Around 18 cubic yards (11.1 X 1.6) of unmixed materials would be needed
-- The following ingredients would be needed for a 1:2:3 mixture:

1. 1/6 x 18 = 3 cubic yards cement
2. 2/6 x 18 = 6 cubic yards sand
3. 3/6 x 18 = 9 cubic yards gravel

Liquid measures of volume

a. Water

-- One gallon equals 231 cubic inches.
-- One barrel equals 31½ gallons.
-- One cubic foot equals 7.48 gallons; equals 62.3 pounds.

b. Small liquid measures

-- One ounce equals 2 tablespoons or 8 teaspoons.
-- Eight ounces equal 1 cup or one-half pint.
-- One pint equals 16 ounces or two cups.

Dry volume measures

a. Cubic feet

-- One cubic foot equals .8 bushel.
-- One bushel equals 1.25 cubic feet.

b. Quarts

Suggested Teaching-Learning Activities

a. Suggested demonstration: How To Calculate Cubic Area

11916

b. Many of these materials can be brought into the classroom and laboratories for students to use.

ABSTRACT - Developed by the Instructional Materials Laboratory at the University of Kentucky, this teaching unit is designed to assist agriculture instructors in planning and teaching competencies in beef production. Contents include: (1) opportunities in beef production, (2) kind of beef production, (3) selecting, (4) feeding, (5) castration and dehorning, (6) internal and external parasites, (7) common diseases, and (8) marketing. References, instructional materials, and teaching activities are suggested for the unit lessons. Appended are 16 overhead transparency masters. (AS)

FARM ANIMALS

UNIT: BEEF PRODUCTION

Major Teaching Objective

To develop the effective ability to produce beef

Learnings (Competencies) To Be Developed

1. To see the possibilities for beef production in our experience programs
2. To determine the kind of beef production to have
3. To select a desirable breed or kind of beef animal
4. To select the breeding animal
5. To select feeder cattle
6. To breed beef animals
7. To feed the breeding cows and heifers
8. To feed young animals
9. To feed fattening animals
10. To care for the cow and calf at calving time
11. To castrate beef calves
12. To dehorn beef calves
13. To control external parasites
14. To control common stomach worms
15. To control common diseases
16. To market beef animals

FARM ANIMALS

UNIT: BEEF PRODUCTION

Suggested Teaching Time

Number of class periods for group teaching:

In classroom, at school . . . . . _____
Outside classroom, at school . . . . . _____
Field trips (away from school) . . . . . _____
Total . . . . . _____

Month(s) _____

Place of the Unit in the Course of Study

Before dealing with any area in this unit, the General Livestock units relating to this area should have been dealt with. This unit is designed to follow the general units. When the how of carrying out certain practices is discussed in the general unit, it is not discussed in this unit. Therefore, it will be necessary to refer to the general units when using this unit.

Some learnings of this unit may be omitted. The thing that will help determine whether a teacher uses a learning is how well it applies to the students' situation. If most students in the class do not have feeder cattle, do not deal with the learning on selecting feeder cattle. The same principle should apply to any other learning.

Suggestions for Introducing the Unit

In introducing this unit, the importance of getting a good start in beef production should be seen. Many farmers do a poor job in beef production. This results in low profit, or no profit.

When sufficient interest is created in the class, ask the students to suggest the things or phases in beef production which will need to be considered. A list similar to the learnings in this unit should be developed. By asking questions and making suggestions, the teacher, with the help of the class, should arrange the learnings in the best order for considering them. If most of the learnings in the unit are secured, perhaps 20 to 30 days will be needed to complete the unit.

Learnings (Competencies) To Be Developed

1. To see the possibilities for beef production in our experience programs

Importance of beef production

MICROCOPY RESOLUTION TEST CHART

NATIONAL BUREAU OF STANDARDS-1963-A

a. Beef is one of the more important meats in the American diet.
b. Kentucky ranks fourteenth nationally in beef cattle numbers.
c. An average of 110 pounds of beef per person was consumed in 1969.
d. There were 2,227,000 beef animals (including calves) on Kentucky farms on January 1, 1970.
e. Kentucky farmers received $209,080,000 cash receipts from cattle and calves in 1968.
f. Twenty-five and three-tenths percent of the total receipts from farm marketings in Kentucky is from sale of cattle and calves (1968 figures). (Source, Animal Science Department, University of Kentucky)

Opportunities in beef

a. Feeder production

-- Feeder production is usually carried on by producers located on land that is generally not suitable for intensive crop production. The land is suitable for producing grass.
-- The calves are usually dropped in early spring and run with the cows on the pasture during the grazing season.
-- The calves are sold as feeders in the fall.
-- Successful feeder production depends largely on having a good supply of cheap forage crops available.

b. Production of slaughter cattle

-- Profits from fattening cattle come from two sources

(1) The selling price above purchase price, which is known as "margin"
(2) The value of increased weight over the cost of the grain

-- The principal reasons cattle feeders have for buying and fattening cattle are:

(1) To receive a higher price for their grain when sold as beef
(2) To market forages and receive income from them that otherwise would be wasted

c. Production of purebred cattle

-- Quality, purebred animals usually bring premium prices.
-- Skill, knowledge, and patience are required for success in the purebred business.
-- A large amount of capital is needed.
-- Large amounts of grain are not essential. Some fattening grains may be desirable.

11921

172 11950

d. The Kentucky cow and calf plan

-- Calves should be dropped in December, January, and February and sold in the fall without wintering them.
-- Cows can be wintered on roughages that are medium to poor quality.
-- This plan requires very little labor.
-- Calves should weigh 600 to 650 pounds when sold.
-- Less capital is needed for this plan than for the purebred business.
-- This plan is designed to use some of the lower quality cows and heifers found in Kentucky.

Personal Interest

a. Beef animals are a source of enjoyment.
b. The producer should be interested in developing an efficient herd.
c. Producers should be enthusiastic in their work.

Advantages of beef production

a. Beef is a very important part of the American diet.
b. Beef animals have the ability to convert coarse forage crops into a palatable and nutritious food.
c. Beef production requires a limited amount of labor.
d. Beef fits well in diversified farming programs.
e. Beef aids in maintaining soil fertility.
f. Beef requires a comparatively small investment in buildings and equipment.
g. Beef production is well adapted to Kentucky farm land.

Disadvantages of beef production

a. Considerable capital is required for the beef business.
b. Income is not distributed evenly throughout the year.
c. A good beef herd cannot be built up quickly.
d. Cattle fattening is often a risky venture.

Suggested Teaching-Learning Activities

a. Suggested problem: What are the possibilities for beef production in our experience programs?
b. Discussion of the learning with the class may be all that is needed in securing this learning.
c. Involve the less able student in terms of explaining and pointing out the importance of the beef industry to the economy of Kentucky Agriculture.
d. Use transparency HS-45-1 as the basis for discussing the various kinds of beef enterprises available.

11922

2. To determine the kind of beef production to have

Possible kinds

a. Feeder production
b. Producing slaughter cattle
c. Purebred production
d. The Kentucky cow and calf plan
e. Others

Available feeds

a. There is a beef program which can be adapted to the conditions found on almost any Kentucky farm.
b. The kind, amount, and cost of feed are important in planning the beef program.
c. Farms that are best adapted to the production of forage crops are generally suited to a beef program that involves the raising of calves and yearlings to be sold as feeder cattle.
d. Land that is well adapted to grain production is suited to fattening feeder cattle.
e. Use farm produced feeds wherever possible, this will keep production costs lower.

Buildings and equipment

a. Buildings and equipment must be considered in any plan for a beef cattle program.
b. The kind and amount of equipment necessary in Kentucky depend upon the type of program planned.
c. Warm barns for calving are not necessary in this state.
d. Cattle feeders need adequate lots, strong fences, plenty of feed bunks, hayracks, and field-storage facilities.

11923

e. Equipment that will permit the effective use of labor is essential for economical production.
f. Provide adequate watering facilities.
g. Provide some kind of windbreak for bad weather conditions.
h. A tobacco barn can be used as a shelter in very bad weather.

Needed capital

a. Some programs require more capital than others and involve greater risk.
b. If we have little capital and cannot afford to take much risk, probably the best program to follow will be the cow and calf program. (This program may be started with a few cows and a good bull. Retain the heifers for breeding and eventually develop a good-size herd. This program is slow, but reasonably safe.)
c. Light cattle ordinarily cost less per head than heavy cattle.
d. Purebred cattle are the most expensive to buy.
e. A well-planned beef program can be financed, so capital should not stand in the way of a sound program.

Available markets

a. We produce cattle to sell and make a profit.
b. Markets develop in areas according to the predominant kinds of animals produced there.
c. The closer one is to an available market, the greater his net sales price will be (price less shipping and other expenses, after shrinkage).
d. The feeder calf sales have proven to be a good market for cattle suitable for those production requirements.

Suggested Teaching-Learning Activities

a. Suggested problem: What kind(s) of beef production should we engage in on our farm?
b. Consider each kind of beef production with the class. Discuss the various aspects of each kind of beef production, and encourage each student to evaluate and decide on a type best suited to the farm situation.
c. Work with the less able student in evaluating these factors, encouraging an objective evaluation. Such special help should result in mastery of the learning.
d. Use transparency HS-45-2 to discuss the learning.

3. To select a desirable breed or kind of beef animal

Different breeds or kinds of animals

a. Hereford
b. Angus
c. Shorthorn
d. Charolais
e. Crossbreds
f. Animals suitable for the Kentucky cow and calf plan
g. Others

Important characteristics of different breeds or kinds of beef cattle

a. Hereford

-- Body form - low set, muscular, compact, broad, and smooth
-- Vigorous animals that are good foragers
-- One breed is polled, the other breed has horns.
-- Good mothers
-- Large animals at maturity
-- Very prolific

b. Angus

-- Polled
-- High resistance to certain eye diseases
-- Calves small at birth, but weaning weights are equal to or greater than those of other breeds
-- Calving difficulties are few
-- Body form -- smooth, broad, low-set, blocky, compact, and well-muscled.
-- Angus cattle frequently bring a slight premium price on Kentucky livestock markets.

c. Shorthorn

-- They are rectangular and compact.
-- They are good milkers.

11925

-- Typically are large animals at maturity
-- They are good foragers.
-- There are both horned and polled strains.

d. Charolais

-- White or cream colored
-- Horned
-- Heavily built and rugged
-- Especially noted for large size at maturity
-- Rapid gainers
-- Efficient foragers
-- Breeding animals are usually high-priced.

e. Crossbreds

-- Vary in characteristics according to breeds involved
-- Usually efficient gainers, "hybrid vigor"

f. Animals suitable for Kentucky cow and calf plan

-- Usually cattle of relatively low quality
-- The dam has considerable dairy blood
--

g. Others

Personal Likes

a. Most cattle breeders have a liking for certain breeds of livestock.
b. Dollar value alone should not determine which breed of cattle one selects. Personal satisfaction and pleasure derived from the work are part of a satisfactory vocation.

Availability of breeding stock

a. Cattle breeders must be continually on the lookout for animals they can bring into the herd to improve their present breeding stock.
b. Good breeding stock should be kept from one's own herd for improvement.

Outlet for surplus animals

a. The number of breeders in an area contributes much to the sale of surplus animals.
b. It is important that one consider the demand before selecting a breed.
c. Grade-herd producers generally find cattle feeders their best market outlet.
d. Purebred producers have more alternative markets available to them.

11926

Environmental conditions under which the animals will be raised

a. Weather, grazing, disease, and insect conditions are important factors in selecting a breed of cattle.
b. Select cattle adapted to the conditions under which they will be raised.
c.

Suggested Teaching-Learning Activities

a. Suggested problem: What breed (or kind) of beef animals should we have?
b. Discuss the relative characteristics of each breed or kind of animal with the class. Have pictures of each breed available for discussion.
c. A field trip to see animals of the various breeds (kinds) would be most helpful with this learning.
d. The pictures and the field trip to see the real animals would be particularly valuable to the less able student. Such visual reinforcement of the audible presentation would be helpful to them.
e. Use transparency HS-45-3 as the basis for launching a discussion of the breeds or kinds of beef animals.

4. To select the breeding animal

Type (body conformation)

11927

11926

a. Animals should be relatively compact and uniform in fleshing.
b. A wide, deep body with good lines, and all parts smoothly blended together are desirable.
c. Evenly fleshed animals with superior development in the regions of the high-priced cuts are desirable.
d. Legs should be straight, strong, and squarely set on the body "corners."
e. Good style, balance, symmetry, and an abundance of quality are very desirable features in a beef animal.
f. Cows should show femininity and breediness, and the bull should show masculinity.
g. Animals should be at least average in size for the breed, with good body length.

Pedigree

a. Family names are important, but do not be misled by them.
b. Poor individuals should not be kept, regardless of the excellence of relatives.
c. When selection is being made between animals of comparable individual merit, the pedigree should be the determining factor.
d. In making use of pedigree selections, ancestors closely related are much more important than those many generations removed.
e. Pedigree records are more important in the purebred business than in commercial beef production.

Performance testing

a. Production testing is the most infallible basis of selection.
b. Performance testing measures the birth weight, weaning weight, daily rate of gain, efficiency of feed utilization, and body type of an animal.
c. Purchase of a "performance tested" bull takes much of the guesswork out of sire selection. Use this means if it is available.

Health

a. Thrifty
b. Vigorous
c. Free from diseases and parasites
d. The cow should appear capable of producing good calves.
e. Tests should be made to be certain the animal is free from tuberculosis, brucellosis, and other contagious diseases.
f. A health certificate from a licensed veterinarian should accompany the animal.
g. Newly acquired animals should be isolated for several days before being turned with the rest of the herd.

Size

a. The most practical size of cattle will vary according to:

-- The kind and amount of feed available
-- The kind of markets available

esert

11928

b. Medium-size cattle tend to combine the gaining ability of large cattle and the finishing ability of small cattle without sacrificing efficiency of gain.
c. Perhaps, under most conditions, medium-type animals are best from the standpoint of widest adaptability, general vigor, reproductive efficiency, milk production, longevity, and marketability.

Age and longevity

a. When buying animals, buy cows with promising calves at their side and that are rebred to a good bull. (A three-in-one proposition.)
b. Heifers may be non-breeders.
c. Heifers usually require more assistance during calving than older cows.
d. Producing cows are culled from the breeding herd at an average age of 9.6 years. Keep a beef cow in the herd as long as she produces good calves.

Condition

a. Avoid buying extremely thin animals.
b. Very fat animals should not be purchased, either.

Defects

a. Poor feet and legs
b. Wry face and tail
c. Blindness
d. Poor teeth
e. "Runty," unthrifty appearance

Reliable source

a. Buy from a reputable breeder.
b. Buy from a source where health and immunization factors are guaranteed.

Reproductive ability

a. Only about 80 percent of bred cows and heifers drop calves. Thus, the other 20 percent are nonproducers (temporarily or permanently).
b. Calf crop percentage is the biggest single factor affecting profit in beef cattle production.
c. Overfeeding or underfeeding may result in temporary sterility.
d. The most common causes of permanent sterility are old age and diseased reproductive organs.

Milking ability (Kentucky cow and calf plan)

a. Good milkers produce heavy, thrifty calves.
b. Poor milkers should be culled.

6811 1190

c. Select cows and bulls whose sire and dam have both produced good milking daughters.
d. Cows producing more milk than the calf can take results in spoiled udders and the loss of a cow.
e. Select a cow with good udder and teat development.

Suggested Teaching-Learning Activities

a. Suggested problem: What kind of breeding animals should we select?
b. This learning may be handled as a well-planned field trip to see some good quality beef animals. Be sure that every important factor in beef cattle selection is covered, if this procedure is used.
c. The field trip setting would be the best way to handle the learning for the less able student.
d. Use transparency HS-45-4 as a summary slide in regard to the four primary factors involved in beef animal selection for breeding purposes.

5. To select feeder cattle

Grades of feeder cattle

a. Prime
b. Choice
c. Good
d. Standard
e. Commercial
f. Utility
g. Inferior

11931

11930

Kind and amount of feed available

a. Liberal amounts of feed grains and good quality forage are usually essential, if high quality beef is to be produced.
b. A cattle feeder with plenty of grain and high quality hay may well consider buying choice grades of beef.
c. It takes both quality cattle and quality feed to produce top beef. (A standard feeder calf will not make a prime slaughter steer.)
d. Low-grade calves, regardless of how well they are fed, will not make high grade slaughter cattle.
e. Commercial to utility grades of beef cattle are well suited for poor-quality feeds.
f. The kind of feed available should determine, to a large extent, the grade of cattle to buy.

Price of feed

a. The price of feed will help determine the size and quality of beef to buy.
b. When feed prices are high and feeder prices low, the cattle feeder expects to make his profits on the margin rather than the gain in weight. Under these conditions heavy cattle (800-1,000 pounds) may be best. These cattle are ready for market after a gain of 200 to 300 pounds.
c. When feed is cheap and feeder cattle high, then the chance for profit is greater on the gain than on the margin. Light feeders (300 to 500 pounds) may then be bought.

Price spread between feeder and slaughter cattle

a. If feeder price is low compared to the price of slaughter cattle, heavy cattle will usually be more profitable.
b. If slaughter price is low compared to the price of feeder cattle, heavy feeders will ordinarily be the best buy.

Future market outlook

a. If the immediate future outlook is good but the long-time outlook is very uncertain, heavy cattle are more certain to make a profit. These cattle may be fed 90 to 120 days and moved before the expected price break.
b. Speculation on the beef market is a risky business.

The length of time cattle are to be fed

a. Amount of feed available usually determines the length of time cattle are fed.
b. Large amounts of feed available are conducive to the purchase of smaller cattle.

11931

11930

Feeder cattle produced on the farm

a. Keep feeders that have the capacity to make economical gains.
b. Select animals that will be one grade higher as slaughter cattle than they were as feeders.
c. Select feeders for grain feeding that would make a feeder cattle grade of Choice or Prime.
d. Select calves that come from good beef-type cows and are sired by a good, meaty bull. (A purebred bull is usually the best.)
e. Select calves that have all beef blood, are large for their age, have good conformation, are thrifty and vigorous, and have reasonably good fleshing.

Suggested Teaching-Learning Activities

a. Suggested problem: What kind of feeder cattle should we select?
b. Study a chart of feeder cattle grades carefully with the class. Explain carefully the major factors which differentiate the grades. The students certainly should know, and be able to recognize, the differences between a Good and Prime animal, for example.
c. A trip to a Stockyard would be most helpful to the class, perhaps as a follow-up to class discussion.
d. Discuss the feeder cattle grades from Transparency HS-45-5.

6. To breed beef animals

Age to breed heifers

The normal age of puberty (when breeding is first possible) is from 8 to 12 months.

11932

b. Breed heifers when they are 15 to 20 months of age.
c. Heifers bred too early will usually have difficulty at calving.

Size to breed heifers

a. Size at first breeding is more important than age.
b. Heifers should weigh 600 pounds or more before they are bred.
c. Heifers bred as yearlings may never reach normal mature size.

The breeding season

a. Turn the bull with the cow herd 9 to 10 months in advance of the desired calving date.
b. Remove the bull from the herd in 90 days. This will help control calving dates and help eliminate late and slow breeders. Females who did not "settle" during this time should be sold.
c. Breed cows (Kentucky cow and calf plan) to calve in December, January, or February.
d. In feeder- calf production, breed cows and heifers to calve in January, February, and March.
e. Fall calving is justified only under special circumstances.
f. Other calving periods may be desirable under certain conditions.

Method of mating

a. Hand mating

- Controlled mating of bull and cow by manually directing the activity.
- Hand mating requires a considerable amount of man labor.
- Is not practical with large commercial herds.

b. Pasture mating

- Turn the bull with cows 9 to 10 months before the desired date of calving.
- Do not leave the bull with the herd more than 90 days
- Probably the most important and useful method for the beef producer.

c. Artificial insemination

- Desirable for a small farm herd of up to 30 cows.
- Probably impractical for large commercial herds with all cows, but could be valuable for the best cows in the herd.
- A bull would prove more economical for large herds, especially under commercial range conditions.

11933

11933

Publications

Kentucky Circular 494 - p. 9.

Visual Materials

Transparency HS-45-6

7. To feed the breeding cows and heifers

Kind of feed

a. Use home-grown feed as much as possible.
b. Feed for beef animals may include:

-- Pasture
-- Hay
-- Silage
-- Grain
-- Protein supplement
-- Mineral mixture
-- Water
-- Feed additives

c. If some poor-quality roughage is to be fed, feed it first and save the best roughage for late winter and the calving season.
d. Pasture is the natural feed for beef cattle, and is all that is usually needed.
e. The breeding cow and heifer must be properly fed and managed if a good calf crop is to be expected.
f.

Amount of feed needed

a. Provide plenty of palatable, nutritious, pasture throughout most of the year.
b. Pregnant beef cows getting plenty of high-quality roughages need no grain or supplement.
c. Mature cows need approximately 2½ pounds of good mixed hay each day per 100 pounds of body weight.
d. Bred heifers need good mixed hay and 3 to 4 pounds of grain per head each day.
e. Providing 8 to 9 months pasture for cows and heifers under Kentucky farm conditions is a reasonable goal.

Suitable rations for cows and heifers

a. Winter rations (cow)

Ration 1
Legume hay, full feed

b. Winter rations (700-1,000 pound heifer)

Ration 1
Good legume hay, 12-15 pounds per day
Poor quality hay, 3-5 pounds per day

11934

- Use of higher quality bulls can result in superior calves from the dam.
- The Breed Associations generally prohibit registration of animals sired by artificial insemination.

Heat period

a. The symptoms of a heat period are:

-- Nervousness
-- Attempts to mount other cows
-- Swelling of the vulva
-- Frequent urination
-- Mucous discharge
-- An inflammed appearance about the lips of the vulva

b. The duration of heat period is usually 12 to 18 hours, although it may vary from 6 to 30 hours.
c. Cows bred near the end of the heat period are more likely to conceive than if bred at other times.
d. The heat period recurs at approximately 20-day intervals.

Gestation period

a. The period of gestation for beef cows is usually around 283 days or about 9½ months.
b. Supply only good pasture and possible some good hay and minerals to the pregnant female. (Special rations are not ordinarily needed.)

Suggested Teaching-Learning Activities

a. Suggested problem: When should we breed our beef animals?
b. Discuss this learning well with the class, for many good beef herds are severely hindered by a poorly managed breeding season.
c. This learning may prove difficult for the less able student to master, as it is rather conceptual in its content. Explain it well, and involve the less able student as far as a potential visual aid, field trip, or some other means of material presentation.
d. Use Transparency HS-45-6 to discuss the three primary methods of beef cattle mating.

Suggested References and Instructional Materials

Beef Cattle Science, pp. 206-213.
Beef Production in the South, Chapter 7.
+Introduction to Livestock Production, Chapters 21 and 31.
Livestock and Poultry Production, pp. 231-233.

11935

Ration 2
Legume hay, full feed
Hay of straw, free choice

Ration 3
Corn silage, 20 pounds per day
Legume hay, free choice

Ration 4
Corn silage
Protein supplement
Low quality roughage

Ration 5

Grass silage
Low quality roughage
Grain

Ration 2
Corn silage, 20 pounds per day
Poor quality hay, 8-10 pounds per day
Protein supplement, 1 pound per day

Ration 3
a. Mixed hay, 18-20 pounds per day
Ground ear corn, 1-2 pounds per day
b. Mixed hay, 17 pounds per day
Ground ear corn, 1-2 pounds per day
Protein supplement, 1 pound per day

Minerals to be included in a good ration:

a. Sodium chloride (salt)
b. Calcium
c. Phosphorous
d. Magnesium
e. Others, as needed

Feed mixed minerals free choice and have an adequate amount of water conveniently located.

Method of feeding

a. Feed minerals free choice to all beef animals.
b. Hay should be fed free choice.
c. The condition, age, and size of the animal will determine the amount of grain to feed. When grain is limited, hand feed cows that need grain.

Suggested Teaching-Learning Activities

a. Suggested problem: How should we feed our female breeding animals?
b. The basic principles of feeding beef cattle are listed in this learning. A more detailed discussion is given in the Unit, "Feeding Livestock," HS-35.
c. Thorough discussion and explanation is needed for the less able student to master this learning. Use the least detailed reference with this student.
d. Transparency HS-45-7 may be used for discussion purposes regarding the kinds of feed to use for the beef breeding animals.

Transparency HS-45-7

8. To feed young animals

Creep-feeding

a. Creep-feeding calves have the following advantages:

-- Calves weigh more at weaning.
-- Cows are less "suckled down."
-- Calves will not miss their mothers as much at weaning time.
-- Calves may be more uniform in size.
-- Calves will be in better condition when they go into the feed lot, and the fattening period may be shortened.
-- Heifers and bulls kept for breeding animals will have more growth.
-- Fat is a good seller of cattle.
-- Creep-feeding permits marketing of early calves on a higher market, usually.

b. Creep-fed calves should gain approximately 1/3 pound per day more than the average calves receiving only milk and pasture.

c. Creep-feeding calves has these disadvantages:

-- Late calves probably will benefit very little from the practice.
-- Under average farm conditions, creep-feeding does not always pay.
-- Creep-fed calves do not gain as well in the feedlot as calves not creep-fed.

11937

-- Manytimes the cost of the feed is such that it, plus the labor required to feed it, is just not a paying proposition.
-- Occasionally calves do not start on the creep well, and much hand labor is needed to get them started.
--

d. Do not creep-feed calves that are to be pastured for 4 months or more after weaning.
e. Creep feeding is somewhat questionable practice under small farm conditions in Kentucky.

Feeds

a. A large variety of feeds may be successfully fed to young animals.
b. The grain mixture for feeding suckling calves on good pasture need not be rich in protein.
c. There is no advantage in grinding corn or oats for suckling calves.
d. When a calf is getting plenty of milk and is on good pasture, it is difficult to get it to eat grain.
e. Corn, oats, barley, sorghum grain, and wheat are good grains for suckling calves.
f. Unless a mixed ration including a protein or antibiotic supplement is to be fed, grinding or rolling corn and oats is not necessary.
g. When calves are kept in a dry lot, it is important that they have a high-grade forage available at all times. Legume hay is preferred.
h. It seems advisable to include aureomycin and stilbestrol in the ration.
i. If the calves do not have access to the mineral mixture fed to the cows, feed minerals in the creep.
j. It takes 3 to 5 pounds of grain to produce a pound of gain on creepfed calves.

Some suggested rations for creep-feeding suckling calves

a. With good pasture and normal milking cows, creep-feeding is not needed because it will not "pay for itself."
b. With poor pasture, low-protein forage, and/or poor-milking cows:

-- Ration 1 -

(1) Shelled or cracked corn - - - - - - - - - 1800 pounds
(2) Soybean meal or (other protein source)- 200 pounds
(3) Antibiotic, per ton of feed - - - - - - 40 grams of aureomycin or its equivalent

-- Ration 2 -

(1) Ground barley - - - - - - - - - - - - - - 800 pounds
(2) Ground sorghum grain - - - - - - - - - - 1000 pounds

11933
11938

(3) A 40 percent commercial protein
Supplement - - - - - - - - - - - - - - - - - - 200 pounds
(4) Antibiotic (as in Ration 1)

Starting Calves to eat

a. Feed cows and calves together for a few days until the calves learn to eat.
b. Place a small amount of feed in the troughs. Remove surplus feed each day. Keep the feed fresh.
c. Begin feeding grain in a creep when calves are 3 to 4 weeks old.
d. The creep should be near shade and water.
e. It should be located in an area frequented by the cows.

Suggested Teaching-Learning Activities

a. Suggested problem: How feed our calves?
b. The students should become aware of the importance of feeding the young animal well. Details on feeding may be found in the Unit, HS-35, "Feeding Livestock."
c. The less able students will be interested in this learning if they have an opportunity to actually feed some animals. A school or class project on feeding might be a very good way to handle this learning.

9. To feed fattening animals

Dry-lot fattening

Roughages

a. Kind of roughages

-- Legume hay
-- Silage
-- Mixed hay or grass hay
-- Stovers and fodders
-- Haylage
-- Cubed roughages

b. The maximum use of silage can best be obtained early in the fattening period.
c. Add protein supplement when a non-legume dry roughage or silage is used. (See general unit for kind and amount of protein supplement.)

Grains

a. Kind of grain

-- Corn
-- Barley
-- Rye (Not more than 1/3 of the grain ration)
-- Oats (Not more than 1/2 of the grain ration)
-- Wheat
-- Grain sorghum

b. The choice of the concentrate ration should be determined by the availability and price of feeds.
c. It usually requires 40 to 50 bushels of corn (or equivalent amount of other grain) and 1/2 ton of good legume hay to fatten a beef steer to Choice grade.
d. Cattle should have free access to salt, and other minerals as well.

Pasture fattening

a. Systems

-- Pasture alone
-- Limited grain allowance
-- Full-feeding grain during the entire pasture period
-- Full or limited grain feeding on pasture following the period of peak pasture growth.
-- Short feeding (60 to 120 days) in the dry lot at the end of the pasture period.

11941 11940

b. Advantages of grain feeding on pasture

-- Pasture gains are cheaper than dry-lot gains.
-- Less labor is required.
-- The maximum fertility value of manure is conserved.
-- Pasture fattening eliminates the need for buildings.

c. Disadvantages of grain feeding on pasture

-- Feeder steers purchased in the spring are usually scarce and high in price.
-- Less labor is available in the summer months.
-- Heat and flies may reduce gains.
-- Pasture may become dry and parched.
-- It takes longer for cattle to reach a desirable finish on pasture.

Getting cattle on full feed

a. Cattle should be started on feed slowly, and gradually brought to full feed.
b. Do not allow cattle to overeat at the start of a fattening ration.
c. Provide plenty of water and comfortable quarters for cattle.
d. Cattle should become adjusted to their new home before grain feeding is started.
e. Feed cattle all the good hay they will eat for 10 to 15 days before starting them on grain.
f. If cattle have never eaten grain, placing grain over roughage will help to get them started.
g. Add one pound of grain per head daily until the cattle are eating 1½ pounds per 100 pounds live weight. Then increase the amount of grain one pound every four days until they are receiving 2 pounds per 100 pounds live weight.
h. If protein supplement is fed, it should be started with the grain.
i. The rate of increase of protein fed will depend on the kind of roughage used.

Some sample rations for four different types of fattening cattle:

a. An emergency wintering ration for young cattle.

-- Legume hay, 5 lbs. per day
-- Low-quality hay, free choice
-- Protein supplement, 1 lb. per day
-- Grain, 2 lbs. per day

b. A wintering ration for steers to be grain-fed on pasture.

-- Legume hay, full feed
-- Grain, 5 to 6 lbs. per day
-- Expected gain, 1.3 lbs. per day

11940

11941

c. A ration for steers on pasture.

-- Pasture (good), 60 to 120 days
-- Grain, full feed on pasture or drylot to 120 days
-- Protein supplement, 2 lbs. per day
-- (Reduce supplement to 1 lb. if 4 to 5 lbs. of legume hay is fed)

d. A dry-lot ration for yearling steers (180-200 days)

-- Corn, full feed
-- Protein supplement, 2 lbs. per day
-- Low quality roughage, 5 to 6 lbs. per day
-- (Reduce protein to 1 lb. when 4 to 5 lbs of legume hay is fed)

e. The above rations were adapted from Kentucky Miscellaneous 140-A.

Economy of feeding

a. Use home-grown feeds when possible.
b. Supply much of the needed protein through good-quality roughages.
c. Determine the most economical protein feed to buy, and feed it.
d. Select the most economical quality mineral mixture to use.

Feed additives

a. Inject steers to be fed with (two 12-mg.) stilbestrol pellets in the fall and again (two 12-mb.) in the spring.
b. Antibiotics and hormones may be used to an advantage if feeding.
c. Consider the use of a tranquilizer in the ration.

Suggested Teaching-Learning Activities

a. Suggested problem: How feed fattening beef animals?
b. The importance of feeding slaughter animals a good ration cannot be overemphasized. Further details may be found in the Unit, HS-35, "Feeding Livestock."
c. An actual feeding test would be very useful in securing this learning, particularly with the less able student. A visit to a commercial cattle feeder would be helpful. Remember, real life situations are the best means of teaching the less able student, or other students for that matter.
d. Use Transparency HS-45-9 as a discussion motivator, exposing each type of feed and discussing them at that time.

10. To care for the cow and calf at calving time

Signs of parturition

a. Probably the first sign is the falling away or sinking in the regions of the tailhead and pin bones and a softening of the flesh in this area.
b. Second, the lips of the vulva will appear swollen and inflammed.
c. Third, there will be an enlargement of the udder and a change from a watery secretion to the thick yellow-colored colostrum.
d. The immediate indications that the cow is about to calve are extreme nervousness, uneasiness, separation from the rest of the herd, and muscular exertion and distress.
e. After a time, the "water bag" appears on the outside and ruptures from the weight of its own contents.

Preparation for calving

a. Provide a good place for the cow to calve

-- During warm weather, a good place for calving is a clean open pasture away from other livestock.
-- A clean, well-bedded, disinfected stall should be provided for cows calving in the barn.

b. Hogs should not run with the cow for they are likely to injure or kill the young calf.

Assisting the cow

a. Observe closely for signs of calving and help cows that are in trouble.

11943

b. After the cow starts to labor, observe closely to see if she is progressing normally. If the cow has severe labor for more than 1 to 2 hours without result, assistance usually is needed.
c. If the cow has difficulty, call the veterinarian or help the cow yourself.
d. When assistance is given:

-- Determine if the calf is in proper position. The front legs should be extended forward with the head resting on or between them. It may be necessary to correct the calf's position.
-- When the calf is in proper position, pull gently outward and upward.
-- Pull only when the cow attempts to labor.
-- The hand and arm should be disinfected before making entry.
-- Be sure there are no scratches or cuts on the hands and arms before entering the cow.

The newborn calf

a. It may be necessary to wipe the mucus from the nostrils to premit breathing.
b. Disinfect the navel of the newborn calf with tincture of iodine to help prevent navel infection.
c. The calf should be rubbed dry if the cow fails to lick it.
d. A weak calf may need help in order to nurse.
e. It is important that young animals receive plenty of sunshine and exercise.

Care of the cow

a. Provide plenty of water for the cow to drink.
b. Remove the afterbirth as soon as the cow has been cleaned, to prevent her from eating it.
c. If the cow does not expel the afterbirth within 48 hours, call the veterinarian.
d. Heavy milkers may need to be milked the first few days.
e. Feed a normal ration in a few days after calving.
f. Poor producers will need extra feed and care.
g. Be on the lookout for milk fever and grass tetany, both are caused by mineral imbalances in the cow. They are not as common in beef cattle as in dairy, however.

Suggested Teaching-Learning Activities

a. Suggested problem: How care for the cow and calf at calving time?
b. The student should understand that rarely is it necessary to assist a cow in calving. In severe cases always contact a veterinarian for professional help.
c. This is a valuable learning in beef cattle production. The less able student should be able to master this learning relatively easily.

11. To castrate beef calves

Reasons

a. More desirable beef development ("marbling" in the lean meat)
b. Longer and more economical gains than with bulls, unless a tranquilizer is used.
c. The animal is quieter and easier to handle.
d. The market presently discriminates against "bull beef," bringing less per pound.

Age

a. From 1 to 3 months old is probably the best time to castrate.
b. The older the animal at the time of the operation, the greater the shock and risk.
c. It is best to castrate in the early spring or late fall to avoid infestation from flies.

Methods

a. Removing the lower end of the scrotum (knife)
b. Slitting the scrotum down the sides (knife)
c. The bloodless methods

Equipment

a. Sharp knife
b. Clamps
c. Elastrator
d.

Materials

a. Disinfectants
b. Smear 62
c. Other good medications

11945

11944

Precautions

a. Disinfect hands, equipment, and scrotum before castrating.
b. Thoroughly clean the calf stall and pen before the calf is castrated.
c. Apply Smear 62 to the scrotum after the operation, to prevent screw-worm infestation.

Suggested Teaching-Learning Activities

a. Suggested problem: How castrate beef calves?
b. Much of this learning can be taught by demonstration.

Steps to follow in preparing for the demonstration.

(1) Select a farm near the school and make proper plans for visiting the farm.
(2) Another possibility is to have a boy in class bring the calves to school for demonstration.
(3) Secure the needed equipment and materials for the demonstration. Do not allow boys to handle the equipment and materials until they are ready to use them.
(4) Arrange the demonstration so that all boys will be able to see.
(5) Demonstrate the method that the boys in class should be using.
(6) The teacher should practice the demonstration before performing it.

Performing the demonstration

(1) Review things discussed in class. Much of this review will be the "why" aspect of castrating.
(2) Explain thoroughly each step performed. Each boy should understand how and why it should be done this way.
(3) Observe the precautions already listed.

c. The demonstration is the best way to secure this learning with all students. The less able student should be able to master this, with adequate teacher help.
d. Transparency HS-45-11 should be helpful in discussing the various castration measures.

Demonstration
- Chart
- Form (To show procedure, steps and materials needed)

12. To dehorn beef calves

Advantages of dehorning

a. Horned cattle are discriminated against on the market, bringing a lower price.
b. More room is needed for horned cattle.
c. Cattle with horns inflict more damage on equipment.
d. There is more danger to the operator in handling cattle with horns.
e. Horned cattle are inclined to keep others away from the feed.
f. Cattle with horns inflict bruises on each other that may result in heavy losses.

Disadvantages

a. Dehorning gives the animal a set-back.
b. Labor and equipment are required.
c. Some death losses occur.
d. Scars may result if the operation is not carefully done.

When to dehorn

a. The age to dehorn depends on conditions and method used in performing the operation.
b. Generally the sooner it can be done the better (a few days after calving).
c. When open wounds result from dehorning, it is better to perform the operation in cool weather. Otherwise, use a good fly repellent on the wound.

Methods (The age of the calf and available facilities determine which to use.)

a. Chemical method

-- Horn buttons may be prevented from growing.
-- A chemical should be used before the calf is 10 days old.

aperi 11947

-- The chemicals most commonly used are caustic potash and caustic soda.
-- Care should be used to prevent severe burns to the calf.
-- Cover the horn button with a dime's thickness of paste. Apply the paste with a stick.

b. Electric dehorners

-- Calves should not be over 3 months old when electric dehorners are used.
-- Apply the electric dehorner to the horn button for 10 seconds.
-- Have someone hold the animal's head securely.

c. Spoons and tubes

-- May be used on calves up to 3 months of age.
-- Sharp tubes of the proper size should be selected.
-- Use a fly repellent on the wound after this method is used.

d. Clippers and saw

-- Use when older cattle are to be dehorned
-- To prevent bleeding, tie off or pull out the main horn artery.
-- Remove about 1/2 inch of skin in order to remove the horn roots.

e. Rubber band

-- The chief advantage of this system is that a large open wound is avoided.
-- The rubber band shuts off circulation and the horn gradually comes off.

f. Preventing horns by breeding to polled bulls is a practical measure.

Precautions to follow in dehorning

a. Apply one of the following

-- Pine-tar
-- Pine-tar and tannic acid
-- EQ 335
-- Smear 62
-- Other good disinfectants

b. Disinfect equipment before dehorning

Suggested Teaching-Learning Activities

a. Suggested problem: How dehorn beef cattle?

eperl

11948

b. A demonstration should follow the class discussion. The preparation for the demonstration and performing the demonstration should be similar to preparing for castrating (listed under learning 11).
c. Once again, a demonstration is the best way to secure this learning with the students. The less able student should be able to master this learning with little difficulty.
d. Use of Transparency HS-45-12 should aid the discussion as to the various methods of dehorning beef cattle.

13. To control external parasites

Common external parasites

a. Screwworm
b. Grubs
c. Cattle lice
d. Flies (horn, stable, face)
e. Ticks
f. Mites
g. Others

Consider these points for each parasite:

a. Parasite
b. Life history
c. Materials
d. How to use materials
e. When to use materials

1192

Some information about the life cycle of each is listed below.

a. Screwworm

-- Adult lays eggs along edge of open wound.
-- Eggs hatch into maggots and burrow into flesh.
-- Maggots feed from 4 to 7 days.
-- Adult worms drop to ground and burrow into soil.
-- They emerge as adult flies a few days later.
-- The life cycle of the screwworm is 21 days.

b. Grubs

-- Adult lays eggs and attach to hair on the heels and legs of cattle in spring and summer.
-- Eggs hatch in a few days, and burrow into the skin.
-- Grubs work their way upward through the muscles and into the body cavities.
-- They finally reach a position just beneath the skin on the back, and make a breathing hole.
-- Six weeks later the larva matures.

c. Cattle lice

-- Adult females glue their eggs to the hair of the host.
-- Eggs hatch in 7-18 days.
-- They reach maturity in 11-23 days.

d. Flies (horn, stable, face)

-- The life cycles of flies are somewhat different; however, they follow the same general pattern (egg, larva, pupa, adult).

e. Ticks

-- Ticks get on the animals to suck blood.

f. Mites

-- The entire life cycle is on the animal's body.

In the unit, Keeping Livestock Healthy, some general factors of controlling external parasites are discussed. The teacher should review with the class the factors listed under Learning 8, before handling a problem on controlling external parasites in beef cattle.

Suggested Teaching-Learning Activities

a. Suggested problem: How control external parasites of beef cattle?
b. Combining all the common external parasites of beef cattle together in one learning seems to be the most efficient use

11921

11950

of time. Thorough discussion of the parasites in question should secure a desirable degree of learning for the class. Special attention to the less able student and involving him in the discussion should cause him to master the learning.

c. Use Transparency HS-45-13-1 to point out the parasites of most concern to beef producers. Transparency HS-45-13-2 may be used as a slide for a chart to be completed on the blackboard by the class. Discussion and use of Kentucky Miscellaneous 280-F is most valuable in completing the chart.

14. To control common stomach worms

Symptoms

a. Lack of growth
b. Loss of weight
c. A fluid accumulation in the lower jaw ("bottled-jaw")
d. Rough hair coat, large abdomen, anemia, and diarrhea

Prevention

a. Proper management and medication
b. Supply the medication to the animals
d. Sanitation is the most important means of prevention.

-- Placing water and feed where it will not be contaminated by droppings
-- Rotate pasture

11951

11920

Treatment

a. Give the medication (use the latest University of Kentucky recommendations)
b. Repeat treatment, as needed.
c. After treatment turn animals on clean pasture.
d. Follow directions on the material that is being used.

Life cycle

a. Eggs of microscopic size pass in feces.
b. Eggs hatch in a few hours under favorable conditions.
c. Larvae reach infective state in 3 to 5 days.
d. Larvae taken into body with food or water.
e. Three to 4 weeks later the larvae reach maturity and produce eggs.

Factors affecting parasite infestation, damage done by parasites, and ways animals become parasite infected are discussed in the Unit, HS-36, Keeping Livestock Healthy.

Suggested Teaching-Learning Activities

a. Suggested problem: How control stomach worms in beef cattle?
b. Securing some samples of stomach worms would be a very helpful teaching aid for this learning.
c. Discuss the economic costs of stomach worms with the class, and be sure that the less able student grasps the importance of a good control program.
d.

15. To control common diseases

Some common infectious diseases

a. Brucellosis
b. Blackleg
c. Shipping Fever
d. Foot Rot
e. Pink Eye

11952

Some common noninfectious diseases

a. Bloat
b. Grass tetany
c. Plant poisoning
d. Tetanus

Consider these aspects of each disease:

a. Disease
b. Cause
c. Symptoms
d. Prevention
e. Treatment

Selected information on common diseases is found below.

a. Brucellosis

-- Caused by Brucella abortus
-- Major symptoms are:

(1) Retained afterbirth
(2) Sterility
(3) Dead fetus
(4) Weak calves

-- Preventive measures are:

(1) Calfhood vaccinate calves
(2) Raise replacements
(3) Practice sanitation
(4) Follow eradication plan recommended by State Department of Agriculture

-- Treatment measures are:

(1) Test
(2) Slaughter infected animals

b. Blackleg

-- Caused by Clostridium chauvoci
-- Major symptoms are:

(1) High fever
(2) Loss of appetite
(3) Lameness
(4) Rapid breathing
(5) Gas-filled swellings on neck, shoulders, and chest
(6) When the swelling is stroked, it makes a cracking sound.
(7) Convulsions before death

11953

-- Preventive measures include:

(1) Vaccinate calves
(2) Burn or bury dead

-- Treatment measures include:

(1) Use anti-blackleg serum
(2) High dosage of antibiotics

c. Shipping fever

-- Caused by Pasteurella bouiseptica
-- Primary symptoms are:

(1) High fever
(2) Loss of appetite
(3) Discharge from nose
(4) Occational cough
(5) Swollen and watery eyes
(6) Stiffened gait
(7) Tongue is sometimes swollen
(8) Difficulty in breathing
(9) Bloody discharge from nostrils

-- Some preventive measures:

(1) Vaccinate with bacterins at least 10 days before shipping
(2) Avoid overexposure and drafty means of transportation

-- Some treatment measures

(1) Use antiserums
(2) Sulfa drugs
(3) High dosage of antibiotics

d. Foot rot

-- Caused by Actinomyces necrophorus
-- Symptoms include:

(1) Lameness
(2) Intense pain
(3) Loss of weight
(4) Milk production falls off
(5) Watery fluid runs from the infected area
(6) Grayish, cheesy discharge
(7) Foul odor

-- Preventive measures:

(1) Dry pastures and clean, dry barns help prevent foot rot
(2) Clean the premises after the trouble, to prevent spreading

-- Treatment measures:

(1) Trim away rotting portion
(2) Apply copper-sulphate solution
(3) Formaldehyde, etc.

11954

e. Pink eye

-- Caused by a virus (?)
-- Primary symptoms are:

(1) Animal sensitive to light
(2) Weakened eyes
(3) Watery eyes and swelling of the lids
(4) Eyeballs may become covered with a white film
(5) Severe pain

-- Preventive measure, segregate infected animals
-- Treatment measures, treat with silver nitrate

f. Bloat

-- Caused by overeating wet clover or lush grass
-- Symptoms include:

(1) Swelling of left flank
(2) Animal moves uneasily
(3) Difficult breathing
(4) Stomach may rupture
(5) Death may come within a few hours

-- Preventive measures:

(1) Feed animal dry hay before turning on legume pasture
(2) Have grass in the pasture mixture
(3) Keep good hay in the fold
(4) Keep cows off legume pasture after a rain

-- Treatment measures:

(1) Walk the animal
(2) Administer a kitchen detergent
(3) Puncture the paunch with a knife in severe cases only
(4) Use latest control measures

g. Grass tetany

-- Caused by a mineral imbalance, primarily related to the magnesium metabolism.
-- Symptoms are:

(1) Nervousness
(2) Loss of coordination
(3) Appetite loss
(4) Staggering and falling
(5) Some symptoms similar to tetanus
(6) If no treatment, coma and usually death
(7) Usually occurs only in early spring on lush, moist pasture conditions.

11955

11924

-- Preventive measures include:

(1) Cleanliness
(2) Keep beef cows in clean quarters or on fresh pasture after parturition
(3) Check all wounds and treat if needed
(4) Keep animal area free of sharp objects
(5) Preventive immunization of animals can be done

-- Treatment includes:

(1) Administer tetanus toxoid
(2) Begin treatment early
(3) Call a veterinarian to administer the toxoid.

In the Unit, "Keeping Livestock Healthy," HS-36, some general measures of controlling common diseases are discussed. The teacher should review with the class the factors involved in Learnings 6 and 7 before handling a problem on controlling common diseases of beef cattle.

Suggested Teaching-Learning Activities

a. Suggested problems: How control common infectious diseases of beef animals? How control common noninfectious diseases of beef animals?
b. The two suggested problems would be useful if thorough discussion was made of each area of beef cattle diseases. Handling them as separate problems would appear to give a more desirable degree of relatedness. A teacher may deal specifically with any diseases that are presently giving trouble in the community. Specific problems on each major disease is probably the best method for teaching the less able student. The general approach will require much more teacher explanation for the less able student.
c. Transparency HS-45-15-1 and HS-45-15-2 should help in focusing the class attention on the two types of beef cattle diseases. They list more common diseases under each type.
c. Use Transparency HS-45-15-3 as an outline for a teacher-student "blackboard conclusion" in chart form. Permit the class to help complete the chart.

Suggested References and Instructional Materials

Books

+Animal Diseases, 1956 Yearbook of Agriculture, Selected references.
Animal Science, Chapter 5 (Selected references).
Beef Cattle Science, pp. 529-576 (Selected references).
Beef Production, pp. 231-232, and 242-256.
Beef Production in the South, Chapter 18.

Livestock and Poultry Production, pp. 414-426.
+Veterinary Guide for Farmers, Selected references.

11956

-- Preventive measures:

(1) Feed good quality legume roughages in spring.
(2) Supply Magnesium oxide mineral to the animals, particularly in early spring.

-- Treatment measures:

(1) Call veterinarian
(2) Intravenous injections of calcium gluconate and magnesium.
(3) Treat within 8-12 hours, otherwise recovery chances are slight.

h. Plant poisoning

-- Many plants may cause poisoning. Most plants are more poisonous at certain stages of growth. An example is fescue (fescue foot).
-- Symptoms include <u>some</u> of the following:

(1) Lameness (fescue foot)
(2) Temperature changes
(3) Nervousness
(4) Unsteady gait
(5) Hemorrhage (usually small)
(6) Diarrhea
(7) "Slobbers"

-- Preventive measures:

(1) Provide good forage, as animals tend not to consume the poisonous plants, as they are not as palatable as pasture plants
(2) Keep an eye on the pastures to look for such problems.

-- Treatment measures:

(1) Call a veterinarian
(2) Remove the animals from the pasture, immediately.

i. Tetanus (lockjaw)

-- Caused by <u>Clostridium tetani</u>
-- Symptoms include:

(1) Often follows deep puncture wounds and operations
(2) Chewing is difficult
(3) Muscle spasms - rigid
(4) Jaws become set - "locked"
(5) Legs spread and stiffen
(6) Tail and ears are elevated and stiff
(7) Death occurs in 7-10 days in up to 90% of untreated cases

Visual Materials

Transparencies HS-45-15-1, HS-45-15-2 and HS-45-15-3

16. To market beef animals

Grades

a. Slaughter grades (steers and heifers)

-- Prime
-- Choice
-- Good
-- Standard
-- Commercial
-- Utility
-- Cutter
-- Canner

b. Stocker and feeder grades

-- Prime
-- Choice
-- Good
-- Standard
-- Commercial
-- Utility
-- Inferior

Market demand

a. The market demands the kind of beef that will furnish a high percentage of the quality cuts that the consumer wants.
b. The consumer wants red meat, with a minimum of fat.
c. High Good to Choice grades furnish the quality of meat the consumer demands.

Time to Sell

a. The amount and kind of feed available will help determine the time to sell.
b. When grain is abundant, the tendency is for long feeding periods.
c. A knowledge of the number of cattle available at a given time, feed conditions, prices of slaughter cattle, and the employment situation will help one determine when to sell.
d. Sell cattle when they are ready to sell.
e. Sell cattle when the market is high.

Factors affecting the market to use

a. Current price per hundred weight
b. Transportation costs
c. Selling price
d. Shrinkage
e. Service rendered by the market
f. Weighing conditions

11958

Handling losses (bruises)

a. Causes of bruises

-- Crowding, bumping and rushing
-- Trampling
-- Cane, whip, and club
-- Horned cattle
-- Other

b. Where bruises occur

-- Bruised areas in the carcass must be trimmed out.
-- The area of the carcass removed cannot be sold for human consumption.
-- The highest percent of bruises occurring on beef animals is in the regions of the most valuable cuts.

(1) loins, 45 percent
(2) rump, 7 percent
(3) round, 12 percent
(4) ribs, 17 percent
(5) shoulder, 11 percent
(6) plates, 8 percent

c. Reducing bruises

-- Drive carefully
-- Inspect load frequently
-- Unload slowly
-- Use canvas slappers
-- Use proper kind of loading chute
-- Do not overload

Suggested Teaching-Learning Activities

a. Suggested problem: How market beef animals?
b. Marketing beef animals is a complex matter, as there are numerous variations as to grades, type of market, and so on. Study of the beef grades and discussion relating to the market use of the animals is helpful in securing high quality learning.
c. Involve the less able student in the discussion relatively early so they will be able to participate.
d. A field trip to a stockyard or cattle sale would be very helpful in securing this learning.
e. Transparency HS-45-16-1 will be helpful in getting the grades before the class for discussion purposes.
f. Use Transparency HS-45-16-2 as a summary once the learning is completed.

ABSTRACT - Developed by the Trade and Industrial Education Division of the District of Columbia public school system in cooperation with curriculum committees, this curriculum guide was developed for instructor use in providing a 3-year (1,620 hours) training program for radio and television technicians at the high school level. Specific objectives include teaching students to read and interpret electronic circuit diagrams, to operate and calibrate test instruments used in electronics, and to perform the skills required of electronic technicians efficiently. Suggested organization, management, and teaching techniques are presented, along with sample instruction sheets and tests. Subject matter blocks, accompanied by a time allotment for each unit outline are: (1) Basic Electronics, (2) Radio Servicing, (3) General Television Servicing, and (4) Television Bench Servicing. Evaluation

Evaluate the unit as to the usefulness in securing desired student learning activities.

The approved practices list developed by the class members should be useful in evaluating the unit. Work with each student in keeping production and feed records accurate and up to date. Figure the feed cost per unit of production with each individual student having a beef enterprise. Teacher visits to the individual student's farm setting is essential in getting the practices adopted by the student.

FOREWORD

This Waiter, Waitress, Hostess guide has been developed for Vocational Home Economics postsecondary training programs in food service occupations.

The guide was prepared by:

Mrs. Anne C. Hayes
Home Economics Specialist
Instructional Materials Laboratory
University of Kentucky
Lexington, Kentucky 40506

The material was prepared in consultation with Miss Mary Bell Vaughan, State Director and Mrs. Sarah T. Henry, Assistant State Director, Home Economics Education, State Department of Education, Frankfort, Kentucky.

Additional ideas and editing of content was done by Mrs. Eliza Read Shettler, Food Service Teacher, Northern Kentucky Vocational School, Covington, Kentucky.

Final editing for the guide was done by Dr. Herbert Bruce, Director, Instructional Materials Laboratory.

The cover was designed by Mr. Raymond Gilmore, Artist, Instructional Materials Laboratory, University of Kentucky.

INTRODUCTION

This guide has been developed to provide training and practice for potential waiter/waitress and hostess work for postsecondary food service training programs for Vocational Home Economics in Kentucky. Upon completion of this course, the trainee should be able to apply general knowledge to specific situations so that he will be a more valuable and a more productive employee in the food service industry.

This guide is used interchangeably with the Basic Food Service Guide. Cross references to the Basic Guide for supporting generalizations, teaching-evaluating strategies, and resources are given in particular units as Orientation; Personal Characteristics; and Safety, Sanitation, Health and Hygiene to avoid repetition. The teaching-learning strategies selected for use should be appropriate for and adapted to meet the needs of the group being taught.

The units included in this guide are: Orientation; Personal Characteristics; Functions of a Waiter, Waitress, Hostess; Supplemental Duties; Safety, Sanitation, Health and Hygiene; and Host/Hostess Responsibilities.

It is the perogative of the teacher as how this material is adapted and used to accomplish the desired objectives for the occupation being taught.

11985

11985

Waiter, Waitress, Hostess

Entry Requirement: Commitment to food service for gainful employment. Meets requirement for food handlers permit.

Program Objective: Train for salable skills as a waiter, waitress, and hostess in restaurants, coffeeshops, cafeterias or other dining services.

Behavioral Objectives: As a result of this program the trainee will:

- identify available occupations.
- demonstrate poise and an attractive appearance.
- practice good working relationships with others.
- demonstrate ability to greet people and escort them to a table
- demonstrate skill in waitress functions such as:
    - presenting menus
    - taking orders
    - relaying orders to kitchen
    - serving courses of food
    - totaling bills
    - accepting payment
- be able to set up and serve banquets.
- identify menu terms and food combinations.
- demonstrate skill in clearing and resetting tables.
- demonstrate skill in loading and carrying trays.
- be able to perform supplemental duties such as:
    - sidework
    - ladling soup
    - tossing salads
    - portioning desserts
    - brewing coffee and tea

11985

11986

- use equipment correctly.
- develop an attitude of good public relations.
- practice acceptable work habits.

Length of Course: 100 clock hours.

UNIT I: Orientation

BEHAVIORAL OBJECTIVE: The student will:

- be able to name available occupations in the food service industry.
- analyze employment policies in a written report.
- practice procedures involved in looking for and interviewing for a job.

BROAD GENERALIZATION: Waiter/Waitress employment affords active, varied, and interesting work for the individual who has the physical ability and personal qualifications to undertake it.

Supporting Generalizations	Teaching-Evaluating Strategies	Resources
1. Refer to Basic Guide, pages 8-10, Supporting Generalizations 1-8. 2. A waiter-waitress may choose a location best suited to his interests. 3. The demand for experienced food service personnel exceeds the supply.	1. Refer to Basic Guide, pages 8-10, Teaching-Evaluating Strategies: 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13 as they apply to waiter, waitress, hostess training. 2. Discuss the changes in modern life which have affected the use of food service operations and the types of service they offer. 3. Refer to Basic Guide, pages 10-11, Teaching-Evaluating Strategies: 14, 15, 16, 17, 18. 4. Develop and discuss an organization chart for more common types of food service operations showing the relation of various functions and the lines of authority. 5. Refer to Basic Guide, page 11, Teaching-Evaluating Strategies: 19, 20, 21, 22.	Refer to Resource List, Basic Guide, pages 8-10. 11882

UNIT III: Functions of a Waiter, Waitress, Hostess

BEHAVIORAL OBJECTIVE: The student will:

- demonstrate ability to greet people and escort them to a table.
- demonstrate skills in waiter/waitress functions.
- use equipment correctly.

BROAD GENERALIZATION: Waiter, waitress, and hostess functions include all activities concerned with customer relations, primarily the selling or merchandising of food and services.

Supporting Generalizations	Teaching-Evaluating Strategies	Resources
1. A waiter/waitress sells service, esteem and satisfaction as well as food. 2. The primary function of the host/hostess is to offer hospitality as a representative of the management. 3. Food service units are usually classified by type of services rendered. 4. The efficienty of the waiter/waitress is measured by the completeness with which he performs his duties before the meal service, before taking the customer's order, after the meal service, and after the customer has left the table.	1. Define - Identify waiter, waitress, and hostess work 2. Discuss the various types of waiters - waitresses such as: - curb waitress - fountain waitress - cafeteria waitress - floor waitress - other 3. Identify the various duties of a waiter - waitress as: - welcoming guests - seating guests - setting up tables - sidework	BULLETINS: Training Food Service Personnel The Waiter and His Public Training Yourself for Food Service Waiter-Waitress Judy The Waitress Nick The Waiter Essentials of Good Table Service

11994

	- order taking - serving orders - cleaning up - others	BOOK: Professional Restaurant Service
	4. Set the classroom up into a restaurant type situation to carry out waiter/waitress functions.	
5. It is the responsibility of food service personnel to meet and seat customers.	5. Role play the reception and seating of customers by a: - waiter - waitress - hostess - others	BULLETINS: Training Food Service Personnel The Waiter and His Public Cinda Service Speaks Out.
	6. Discuss the differences and similarities of the seating of guests by each of the above.	
6. The waiter/waitress should be familiar with the menu content, its arrangement and its prices. 7. The menu tells the customer what is available, how it is prepared and how much it costs.	7. Demonstrate and practice the correct method for presenting a menu to a customer. 8. Discuss reasons why waiters/waitresses need to be familiar with items on the menu. 9. Define various terms used on menus as: - appetizer - entrée - au jour - à la mode - au jus - others 10. Using a matching quiz, have trainees check their knowledge of menu terms.	BOOKS: Professional Restaurant Service A Cook's Quiz Menu Dictionary, Multilingual Glossary of French Culinary Terminology, Foods and Confections

11998

	11. Show the difference in table d'hôte and à la carte menus and service using actual menus or charts.	
8. The waiter/waitress should know basic information regarding items on the menus.	12. Have class members develop a check list for checking through the menu. Things to be included might be: - availability of items - neatness, cleanliness, legibility - terminology of items - à la carte and table d'hôte items - food substitutions on à la carte and dinner items - prices	
9. The waiter/waitress should be informed concerning the methods of preparing the food item he serves.	13. Dramatize situations in which a waiter/waitress gives an explanation about the menu to a customer. 14. Use a tape recorder to evaluate class members' ability to speak clearly and to provide correct information. 15. Demonstrate and role play the taking of a customer's food order.	BULLETINS: <u>Training Food Service Personnel</u> <u>The Waiter and His Public</u> <u>Cinda Service Speaks Out</u> . FILM: "Taking The Order"
10. A waiter/waitress may help the customer by either giving him information or making suggestions regarding food selection.	16. Discuss or role play how to assist a customer in making a decision and when he asks, "What's good today?" 17. Discuss: "What information does a customer have a right to expect from a waiter/waitress?" 18. Demonstrate the proper method for writing up of orders on an order pad.	

11996

11. A check is used as a means of recording the order, as the customer's bill, and as a source of information about the sale.

12. Good service is an important factor in attracting and keeping patronage.

13. Each food service operation has certain policies of operation and standards of service.

14. There are several methods of table service and each food service unit should follow the method suitable to its particular conditions.

19. Have class members practice taking orders and checking written orders for:

- proper technique
- table number
- abbreviations
- systematic system
- legibility
- combined or separate checks
- when to serve beverage

20. Discuss techniques that add to making a meal more pleasant such as:

- prompt service
- pleasant attitude
- refilling of water glass
- refilling of beverages
- ease in caring for accidents
- attentive attitude

21. In relation to table set-ups define:

- cover
- edge of cloth
- set line

22. Research, demonstrate, and discuss typical table settings as:

- simple breakfast
- complex breakfast
- lunch
- simple dinner
- complex dinner
- soup and sandwich
- salad
- salad and sandwich
- dessert
- side dish placement

15. The waiter/waitress should provide tables that are properly set before service is given.

23. Have class members draw each setting and practice each type of setting.

24. Use diagrams, transparencies, flannelboard, etc. of a series of cover set ups to illustrate table settings. Discuss each and the reason for each appointment.

25. Have class members to practice setting a variety of table settings using various menus to determine appointments used.

26. Demonstrate and practice the placement of additional silverware for a dinner menu requiring pieces such as:

- cocktail fork
- soup spoon
- dessert spoon
- parfait spoon
- butter knife
- others

27. Using sample menus consisting of three or four courses, have class members make a list of equipment and accompaniments needed to serve each course.

28. Demonstrate and have trainees practice until they can quickly lay linen and fold napkins in the standard form and with fancy variations.

FOREWORD

A General Statement of the Trade

Electronics has steadily and progressively transformed the Modern Age, from which we are currently moving, into an age of wonder; a world of dreams come true; a fairyland in which there lives a race of men who can see beyond the horizon and great distances; communicate great distances. These men travel to the "Never Never Land" of space; their mechanical slaves obey their wishes, solve their problems and predict the future. The difference between this age and the magic of fairytales is that instead of fast-moving giants, all-knowing fairies, all-hearing witches, all-seeing elves, and crystal balls, there are gadgets called television, radio, radar, computers and a host of other electronic devices.

It seems likely that this new age will be referred to by future generations as the "Age of Electronics." Our progress in this new age will depend upon the quality and number of scientists, engineers, and technicians we can produce. The need for technicians to construct, install, maintain and service electronic equipment continues to grow as more and more products are produced.

This course is designed to help fulfill the need for technicians by providing students with the knowledge and skills needed for successful entrance into the trade areas of Television and Radio. It will also provide them with a foundation on which they can build additional competence in these areas and those allied to them.

Prerequisites of Entrance Into the Trade

A thorough knowledge of mathematics and science is needed by the technician to aid in the solution of problems in the daily performance of duties. Jobs sometime require long hours of painstaking manipulation. Therefore, students entering training in this trade should have an aptitude for math and science, and a willingness to work hard. Instruction begins with the assumption that the student has completed the ninth grade and can do average or better than average work.

Time Required to Complete the Course

The time requirement for a high school diploma and a certificate in the Radio and Television course is three (3) years. Laboratory practice or shop work is scheduled for three (3) clock hours daily, 15 hours per week. One and one-half hours per day are spent in related subjects--science, mathematics and/or art. One and one-half hours are spent in academic subjects. Five hundred and forty (540) hours are spent in shop work per year -- a total of 1620 hours for the three year course.

17. Unusual and difficult customers should be handled with intelligence, tact, and good judgment.	38. Identify unusual and difficult customers such as: - blind people - deaf people - diabetics - hand injury - intoxicated people - boisterous people - others	FILM: "Courtesy: The Inside Story"
	39. Role play correct methods to use in assisting and serving an unusual and difficult customer.	
	40. Provide class members mimeographed outlines of detailed serving instructions.	BULLETIN: <u>Training Food Service Personnel</u>
	41. Evaluation: Have class members select a menu for a special group and make out the linen order, dish list, table setting, work schedule and serving directions.	FILM:
	42. Resource person or chef from an established restaurant to explain the method of placing kitchen orders.	"Introducing Alice: A Good Waitress"
18. Giving and collecting orders in the kitchen vary with the organization, layout, and regulations of the food service unit.	<u>Field Experience</u> 43. Visit several types of food service establishments to observe kitchen ordering system, proper assembling of an order and sequence used for ordering and picking up order.	
	44. Have students demonstrate good and bad methods of calling orders.	BULLETINS: <u>Training Food Service Personnel</u>

12000

19. The kitchen and dining room layout and the type of food service affect the duties assigned to waiters/waitress and the manner in which these duties are performed.	45. Record calling of orders and have class evaluate them.	The Waiter and His Public Cinda Service Speaks Out . .
	46. Observe various kitchen and dining room layouts illustrating the location of various departments and how this affects the giving and assembling of an order.	
	47. Demonstrate and have class members practice assembling an order, loading, and carrying a tray.	BOOK: Professional Restaurant Service
	48. Discuss: "What is the arm service method?"	
	49. Demonstrate and have class members practice the arm service method in terms of: - stacking technique - posture - walking - precautions	
20. A tray should be loaded so that it is evenly balanced and objects will not slip or spill while being carried.	50. Demonstrate and have class practice: - loading a tray with soiled dishes - unloading a tray with soiled dishes in the dish room - carrying a tray with both hands at waist level - balancing a tray at shoulder level - clearing a table when guests are seated - changing the cloth and resetting the table when guests are seated - performing various cleaning operations	BULLETIN: Training Food Service Personnel
21. The check should be accurately totaled, laid face down on the table or on a small change tray and presented after the last course has been served or as soon as the guest has finished eating.	51. Discuss the basic techniques of presenting a check with consideration given to: - a timing procedure - house policy for writing final check - answering questions about charges on the check	BULLETINS: Training Food Service Personnel Cinda Service Speaks Out . .

12001

15001

22. The cashier should be careful and honest in handling money, quick and accurate in making change and courteous and considerate in dealing with customers.

23. The cashier should be intelligent and tactful in meeting various situations related to handling of the money.

12002

52. Practice presenting a check for a variety of situations as:

- two or more people -- men and women
- couples
- group - age, men, women, both
- others

53. Demonstrate cashing methods for payment of bill.

54. Practice using equipment such as:

- adding machine
- cash register
- change maker

55. View film, "Handling Money".

56. View slides, "Making Change".

57. Role play situations illustrating a cashier-customer relation in situations as:

- receiving cash and making change
- cashing a traveler's check
- giving directions to a local point of interest
- accepting praise or compliments about the food or service

58. Visit local tourist attractions to increase information about local points of interest.

59. View filmstrip, "Change on the Table".

UNIT IV: Supplemental Duties

BEHAVIORAL OBJECTIVE: The student will:

- develop ability to perform supplemental duties.
- demonstrate setting up and serving banquets.

BROAD GNERALIZATION: The functions of a waiter/waitress varies with the size of the operation and the standards of service.

Supporting Generalizations	Teaching-Evaluating Strategies	Resources
1. Waiter/waitress have certain duties to perform other than actual serving of food referred to as "side work."	1. Define and identify side work duties. 2. Discuss side work duties stressing: - emptying and refilling sugar bowls - filling salt and pepper shakers - filling syrup jugs - cleaning condiment bottles - folding napkins - arranging menus - arranging flowers - filling creamers - cleaning ashtrays - cleaning serving trays - preparing ice - cutting butter - dusting chairs - cleaning flatware - checking cracker containers	BULLETINS: Waiter - Waitress Training Food Service Personnel Correct Waitress BOOK: Professional Restaurant Service

12004

2. The waiter/waitress can make the task easier and more valuable by adapting good work habits.	3. Have an experienced person demonstrate the correct method for performing "side work" duties such as: - ladling soup - tossing salads - portioning desserts - others	SLIDES: "Cutting a Pie" "Dipped Salad Assembly"
	4. Have class members practice performing various "side work" duties.	
3. The service station saves many trips to the kitchen. 4. Service stations should be kept neat and orderly and well stocked.	5. Collect photographs of dining room service stations and discuss arrangement, equipment, and supplies needed. 6. Discuss and practice in class the cleaning and storage of supplies in the service station.	FILM: "The Side Stand"
	7. Discuss types of special parties and the service for these as: - small dinner party - banquet - buffets 8. Practice making out reservation forms for special events. 9. Observe and discuss: "What is a buffet type of service?" 10. Discuss the purpose of the buffet service. 11. Study the table settings for buffet service.	BULLETINS: Training Food Service Personnel The Waiter and His Public

00051

12005

ISOOP

	12. Have class members practice setting a buffet service for: - breakfast - luncheon - dinner	
	13. Prepare a buffet meal and practice serving for a group of people.	
	14. Discuss "What is a banquet type of service?"	
	15. Study table set up for banquets.	
	16. Discuss and set up a work plan for serving a banquet.	
	17. Arrange to serve at a banquet for a local organization.	
5. Room service is an important part of the food service operation in hotels.	18. Discuss room service and the correct procedure for this form of meal service.	
6. There are several forms of service in use in restaurants and dining rooms with the set-up and service procedure characteristic of each type.	19. Discuss special forms of service which might be used in restaurants and dining rooms such as: - English service - American service - French service - Russian service	BOOK: <u>Professional Restaurant Service</u> BULLETINS: <u>Training Food Service Personnel</u> <u>Cinda Service Speaks Out--- About Your Career as a Sales Hostess</u>
	20. Visit various restaurants and observe special forms of service in use.	
7. Table decorations add to a more pleasant surrounding during mealtime.	21. Have resource person to demonstrate inexpensive table decorations using flowers, candles, etc. Practice using these during class laboratory work.	BULLETIN: <u>Training Food Service Personnel</u>
8. Busboys help prepare the dining rooms for service, provide equipment, and supplies for waiters/waitresses and assist in restoring order to the dining room after the serving period has ended.	22. Observe the duties of a busboy in relation to various types of operations.	FILM: "Mr. Busboy"

12006

ISOOR

UNIT V: Safety, Sanitation, Health and Hygiene

BEHAVIORAL OBJECTIVE: The student will:

- develop an appreciation for safety, good work habits, health laws, and sanitation as they apply these to food service.

BROAD GENERALIZATION: High standards of hygiene and sanitary work habits must be maintained by all workers if food service is to meet its obligation of serving safe, wholesome foods.

Supporting Generalizations	Teaching-Evaluating Strategies	Resources
1. Refer to Basic Guide, pages 40-45, Generalizations: 1, 2, 3, 4, 5, 7, 9, 11, 12.	1. Refer to Basic Guide, pages 40-45, Teaching-Evaluating Strategies: 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 12, 16, 17, 20, 25, 26, 27, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39.	Refer to Basic Guide, pages 40-45, Resources. FILM: "The Invaders" BULLETIN: <u>Sanitation Follies</u>

12007

UNIT VI: Host/Hostess Responsibilities

BEHAVIORAL OBJECTIVE: The student will:

- understand responsibilities to be performed by a hostess in a food service establishment.

BROAD GENERALIZATION: The responsibilities of the host/hostess include working with all personnel in the food service establishment, to maintain relationships with customers and to assist in providing an efficient food service operation.

Supporting Generalizations	Teaching-Evaluating Strategies	Resources
1. The food service host/hostess generally supervises dining room service and waiters/waitresses.	1. Define the position of a host/hostess in the food service industry.	BULLETINS: <u>Training Food Service Personnel</u> <u>Waiter-Waitress</u>
2. The host/hostess should be poised, well-groomed, use good English, and have a working relationship with all individuals concerned with food service.	2. Discuss desirable qualities for a host/hostess.	
3. The host/hostess is responsible for the appearance, cleanliness, and order of the dining room during the serving period.	3. List and discuss the duties of a host/hostess.	
	4. Demonstrate and practice the duties of a host/hostess: - inspecting the dining room - inspecting personnel - checking menus - instructing waiters/waitresses in daily activities - greeting and seating guests - taking reservations by phone - others	

12008

0.051 ISO

4. The host/hostess functions include pre-service, service and post service activities.

5. The host/hostess represents management in the minds of most poeple.

6. The techniques used with telephone customers determine if he will frequent the food service establishment.

7. A host/hostess should be familiar with local attractions and needed directions for tourists.

5. Display and discuss schedules of work, station diagrams, and serving directions.

6. Practice making out work schedules and instructions diagrams, and serving directions.

7. Study and discuss making out timesheets, linen reports, sales analysis, and rating sheets for waiters/waitresses.

8. Research and role play situations illustrating a point of conduct for a host/hostess such as:

   - explaining new regulations to waiters/waitresses
   - manager - host/hostess conference in which the manager gives friendly, constructive criticism and the hostess accepts it
   - host/hostess soothing a troublesome guest
   - host/hostess meeting an emergency situation such as spilled soup, etc.

9. Discuss closing duties for a host/hostess.

10. Role play the proper techniques for talking to customers over the telephone. Use tape recorder and analyze.

11. Role play giving information about direction, local attractions, accommodations, etc.

12. Visit each local tourist attraction to increase information about local points of interest.

ABSTRACT - Individually authored in cooperation with the University of Kentucky, Department of Vocational Education, this unit is for teacher use in planning and teaching a 10-12 day unit for grade 11 or 12, which is concerned with agricultural business in marketing, purchasing, and using agricultural goods and services. Designed tc be the major tool for teaching economics where production agriculture is limited or where farm management is not taught, the unit is organized into eight competency areas. Suggested references, instructional materials, and teaching-learning activities are included as well as nine transparency masters keyed to the competency areas. (RR)

UNIT (MODULE): AGRICULTURAL BUSINESSES IN THE AMERICAN ECONOMIC SYSTEM

Major Teaching Objective

To develop the understanding necessary for students to make effective use of agricultural businesses in marketing, purchasing, and using agricultural goods and services.

Suggested Learnings (Competencies) To Be Developed

1. To know the importance of agriculture in our total economy
2. To know what it takes to make an agricultural business function
3. To be aware of the different kinds of businesses serving agriculture
4. To understand how a business (owned by one person or by a partnership) is set up and operated
5. To understand how a business corporation is set up and operated
6. To understand how cooperative businesses are set up and operated
7. To know how the member-patron of a cooperative business differs from the customer of a business that is not a cooperative
8. To make use of farmer cooperatives to increase net farm income

UNITS (MODULE): AGRICULTURAL BUSINESSES IN THE AMERICAN ECONOMIC SYSTEM

Suggested Teaching Time

Number of class periods for group teaching:

In classroom, at school . . . . . _____
Outside classroom, at school. . . . . _____
Field trips (away from school). . . . . _____
Total . . . . . _____

Month(s) _____

Place of the Unit in the Course of Study

This unit is designed to teach some basic understanding of business and economics as they relate to agriculture in the high school vocational agriculture courses of study. It should generally be a part of a senior, or possibly junior, course of study. It may be the major Economics teaching tool in areas where production agriculture is limited, or where farm management is not taught. It may be used to complement a good farm management course, as well. Regardless of where it is used, it should develop the understanding necessary for students to make effective use of agricultural businesses in marketing, purchasing, and using agricultural goods and services.

Suggestions for Introducing the Unit

In introducing this unit, the students should be caused to understand how important the business field is in the marketing, purchasing, and supplying of agricultural goods and services. They should be made aware of the fact that there are four major ways of organizing businesses, with the government constituting perhaps a fifth major type. The student should be made aware that each type of business has some advantages and disadvantages.

This unit has three learnings on cooperatives. Learnings seven and eight are included for the convenience of the departments who choose to participate in the Kentucky Youth Seminar program sponsored by the University of Kentucky, The Kentucky Cooperative Council, Inc., and the State Department of Education. They are sound in their content, and should prove valuable even if a department chooses not to offically enter the Seminar program.

It is envisioned that this unit may be handled in from ten to twenty days, depending upon the objective of the teacher.

12017

Learnings (Competencies) To Be Developed

1. To know the importance of agriculture in our total economy

Agriculture is more than farming

a. About 35-40 percent of all gainfully employed workers in the United States work in industries that serve agriculture.
b. Approximately 25 percent of our total national income is from farm-related businesses.
c. Farming is only one kind of agricultural business.

Agriculture is a vital part of our total business economy

a. Many basic commodities come from the farm.
b. Advances in processing, storing, and distribution have made basic farm products produced in any area readily available to all United States consumers.
c. Kentucky ranks twenty-third among the states in cash receipts from Farm Marketings- (1968 - $825,000,000).

Farming continually makes important contributions to our national development

a. The productivity of our farmers helped make it possible for our great industrial business development.
b. The key leaders in the founding history of our country were farmers (George Washington, Thomas Jefferson, etc.)
c. Although fewer people are engaged in farming each year, the average size of the individual farm continues to increase. The average size farm in the U.S. in 1968 was 369 acres. (Kentucky-126 acres.)
d. Today, fewer U.S. Farmers produce more than ever before in any nation's history.
e. Farm employment in 1968 was listed as 3,800,000..

Business serves people

a. Business interactions provide the basic necessities of life--food, clothing, and shelter.
b. The many goods and services made possible by businesses in the United States has resulted in our people enjoying one of the highest levels of living in the world.
c. Business provides important services to people--education, transportation, communication, health, etc.
d. Through specialization and mass-production methods, business produces goods and services at prices people can afford to pay.

12018

Our economy is big and complex, and the various parts are dependent on each other

a. Farming is dependent on many other industries (petroleum, machinery, chemicals, etc.)
b. These industries depend on farming for much of their income.
c. Specialization has led to mechanization and efficiency in industrial businesses, as well as in agricultural businesses.
d. An individual farmer exercises little influence in buying or selling. He is small in relationship to the businesses with which he must deal.

Suggested Teaching-Learning Activities

a. Suggested problem: How important is agriculture in our economy?
b. Discuss this learning well. Use of a problem may not be necessary if you get good class discussion.
c. In introducing this unit, ask the more obvious questions and pull the simpler ideas from the disadvantaged and handicapped students in your class. These students can respond to simple questions, so you may desire to give them an opportunity to participate.

2. To know what it takes to make an agricultural business function

The production of goods and services is a complex process. This process is dependent primarily upon these basic factors:

a. National resources--are those physical and climatic features of the earth which cannot be created (or changed to any great degree) by man.

(1) Soil and climatic conditions are basic to all agricultural production.
(2) The production efficiency of some natural resources can be increased by man through such practices as irrigation, drainage, mechanization and soil fertilizations.
(3) The earth's surface is the source of oil, coal, and metal ores.

12020

I. OBJECTIVES

Note: It should be kept in mind that vocational-industrial education, as it is known today, is not designed to develop skilled craftsmen as such. It is intended, through preparatory programs in basic fundamentals, to bring students to the entrance point of wage-earning ability at advanced apprenticeship level. Rapid advancement thereafter (toward thorough understanding and skilled craftsmanship levels) is accomplished through actual work on the job and night supplementary trade-extension courses.

General

The general objectives of the courses of study in Trade and Industrial Education are to develop in the students the abilities to:

Do the various manipulative skills that will permit their initial employment in the industry, rapidly increase their efficiency, and promote their advancement in the salary scale.

Understand the application of basic principles of the science, mathematics, and related technical knowledge that condition the manipulative skills.

Appreciate the social and industrial relationships in connection with the contribution which a worker can make in the areas of health, effective services, and general social-industrial and public relations.

Specific

The specific objectives of the course of study in Radio and Television are designed to enable students to:

Read and interpret electronic circuit diagrams.

Operate and calibrate test instruments used in electronics.

Select and use the tools and equipment of the trade effectively and efficiently.

Understand the language of the trade and read and interpret trade literature.

Understand the health and safety hazards involved in electronics and to observe safe work practices.

Amend their knowledge and skills.

Profit from advanced courses in Radio-Television or allied courses requiring a strong foundation in electronics.

Perform the skills required of electronic technicians efficiently.

Make intelligent decisions in the performance of his duties.

Appreciate the accomplishments of thinkers in the field and the progress that has been and will be made.

Work harmoniously with others and be good citizens in their communities.

b. Labor--is an essential factor in any business.

(1) Labor is a very critical factor in agricultural production.
(2) Agricultural labor is often hard work, and other employment offers equal or better wages for a less demanding type of labor.
(3) Labor specialization usually develops skill and efficiency.

c. Capital is needed for all forms of business. Providing services requires capital.

(1) Capital is primarily in three forms--property (land, building, machines, tools, etc.), investments, and cash.
(2) Capital resources are essential for the operation of any business and may be a matter of national and state concern (railroads, highways, etc.).

d. Management is the biggest challenge in any business.

(1) Without good management, the other resources are of little value.
(2) Management is usually involved with profitability.
(3) Management involves putting the other resources to work and using them to achieve the greatest results or production level, or long-term profitability.

e. Effective marketing and purchasing increase farming income.

(1) The difference between what the farmer gets and what the consumer pays for agricultural products (and the things made from them) goes to the marketing firms and agencies.
(2) Opportunities exist for farmers to bargain collectively or to do more of the marketing job or purchasing job and thereby increase their net income.

Suggested Teaching-Learning Activities

a. Suggested problem: What causes an agricultural business to function?
b. Use of Transparency HS-76-2-1 should help understanding of this learning. It should prove valuable for understanding by the handicapped and disadvantaged group as it simplifies production greatly.
c. Use of Slides 1 and 2 from "Cooperatives and Their Business Neighbors" Slide Set would also be helpful on this learning.

Suggested References and Instructional Materials

Books

Exploring Agribusiness, pp. 9-20.

Publications

"How We Organize To Do Business in America," pp. 16-17.

Visual Materials

Transparency HS-76-2-1
Slides 1, 2 from Slide Set - "Cooperatives and Their Business Neighbors."

3. To be aware of the different kind of businesses serving agriculture

Broadly speaking, there are four functional types of business involving agriculture.

a. Production of basic materials (farming, mining, etc.)
b. Processing or manufacturing businesses (Meat Packing Company, Cloth producing company, etc.)
c. Distribution of goods (Southern States Coop, etc.)
d. Providing services (finance, education, entertainment, etc.)

All these share features in common

a. Competition is an essential feature of American business.
b. The operation of business from within its own organization, competition, and private ownership (rather than State ownership) are essential features of American business.

Business in the United States is conducted by:

a. Individual ownership (single proprietorship).
b. Partnerships
c. Regular business corporations
d. Cooperative business corporations
e. Government (the Nation's number 1 employer, as well as consumer of goods)

Suggested Teaching-Learning Activities

a. Suggested problem: What are the different kinds of businesses serving agriculture?
b. Use of HS-76-3-1 Transparency should prove helpful in making clear to the handicapped and disadvantaged what the "Four Main Functional Types of Business are. The labels on the sample businesses should aid them in retaining this material.
c. Use of HS-76-3-2 Transparency should be useful in pointing out the Five Basic Types of Businesses to the less able student, as well as the average and superior student. The pictures and label-on each type of business should be helpful to the less able student.

15055

d. Use of HS-76-3-3 Transparency should be helpful in challenging the able student to do additional individual work. It may prove useful to the less able student as well as guiding his thinking on "Questions Relative to Any Business." Read over and explain each question thoroughly.
e. The Slide Set, "The American Private Enterprise System," may be used here to show the entire business spectrum from beginning to end. It may be more easily understood by the able student than the less able student.
f. Use Slide number 3, of the Slide Set, "Cooperatives and Their Business Neighbors." This slide should prove valuable to the less able student in helping him to conceptualize the types of businesses in our country.

Slide number 3 from the Slide Set, "Cooperatives and Their Business Neighbors"
The entire Slide Set, "The American Private Enterprise System"

4. To understand how a business (owned by one person or by a partnership) is set up and operated

Ownership and management features

a. Business is owned by one person or by partners, who share in ownership and management.
b. The owners have complete control of the business (as long as they operate on a legal basis).
c. All decisions are made by owner(s).
d. Policy is determined by owner(s)

12022

12021

Financial responsibility of the business

a. The responsibility to supply the necessary capital rests with the owner(s).
b. All risks are assumed by the owner(s).
c. The profits are received by the owner(s).
d. The liability of the business rests upon the owner(s). The owner(s) suffer any loss which may occur.

Special features of individual proprietorships

a. This is the simpliest form of business to own or operate.
b. As business expands, over all management becomes a problem.
c. There are limited employee opportunities as the business is not permanent.
d. Business ordinarily ends if anything happens to owner.

Special features of partnerships

a. General partnerships. All partners participate in the operation of business, sharing all responsibilities including unlimited liability for debts, etc. Each partner is held personally responsible for all the debts of the business, even those incurred by the other partner(s) and without the first partner's consent. Each partner is also bound by the agreements made for the business by the other partner(s).
b. Limited partnerships. This partnership is characterized by limited liability of one or more partners. However, there must always be at least one partner in a limited partnership who is subject to unlimited personal liability. There is no limitation on the number of limited partners, providing there is at least one general partner in the firm. Withdrawal of a limited partner may not dissolve the firm, but withdrawal of a general partner does.

Single proprietorships and partnerships are the most common type of business in the United States. There is also a tendency for these types of business to be relatively small.

a. The farm is usually a sole proprietorship or a partnership business.
b. Many agricultural businesses dealing directly with farmers are owned and operated as single proprietorships or partnerships.

Suggested Teaching-Learning Activities

a. Suggested problem: How does a single owner or partnership business function?
b. Invite a representative of one of these types of business to talk with the class.

12023

c. Use of Transparency, HS-76-4-1, should be very helpful in pointing out the similarities, and differences, of these two important types of business. Seeing this visual should prove useful to the handicapped and disadvantaged student in conceptualizing this learning in his mind.
d. Use Slide numbers 4, 5, 6, and 7 from the Slide Set, "Cooperatives and Their Business Neighbors." These slides should prove valuable in making concrete this learning to the class. Careful explanation of this series of slides is important in teaching the less able student.

Suggested References and Instructional Materials

"How We Organize To Do Business In America," pp. 20-23.
"Four Methods of Doing Business," pp. 3-10, 12-18.
"Cooperatives in Agribusiness," pp. 5, 7.

Visual Materials

Transparency HS-76-4-1
Slide numbers 4-7 from Slide Set, "Cooperatives and Their Business Neighbors"

5. To understand how a business corporation is set up and operated

One unique feature is that this type of business is treated by law as a "legal person." Members own the corporation by holding shares of stock, and are not individually responsible to the law like owners in a partnership.

Business corporations are the symbols of America's capitalistic system, free enterprise, and the world of "big business." Corporations produce about 57 percent of the total income, more than all other sources combined. About fifty percent of the labor force, excluding farm workers, are on corporation payrolls.

A corporation continues to operate smoothly with the death or withdrawal of some of the owners.

A corporation may be either a stock or a non-stock corporation.

a. A stock corporation is one that issues capital stock representing shares of ownership.
b. A non-stock corporation is a private corporation that is not necessarily concerned with profit. It may have no capital and issue no ownership shares. (A farm corporation would be of this type.)

12023

Features of a business corporation

a. Ownership is by shares of stock.
b. The business is operated and policy determined by an elected board of directors. This board employs a president, secretary, treasurer, and other officers to manage the business.
c. Capital for the business comes from the sale of stock and from returns of goods and services provided.
d. Voting by stockholders and dividends (returns) paid to the stockholders are in proportion to their ownership (the number of shares of stock they own).
e. In a business failure the corporation is liable to the full extent of its assets. Each stockholder, however, cannot lose more than he has invested in stock, plus his share of the growth value of the business.
f. The services and goods provided by a regular business corporation are for the most part not primarily for the stockholders, but are for the general public. The stockholder's primary motive in the regular business corporation is profit (investment).
g. Corporations are subject to taxation in much the same way as is an individual. Corporations usually pay Federal Tax at a rate of 22% on the first $25,000 profit, and 48% on the remaining profit.

Suggested Teaching-Learning Activities

a. Suggested problem: How is a corporation operated?
b. Invite in a representative of a local business corporation to discuss with the class some aspects of the business.
c. The use of Transparency HS-76-5-1 should help in getting the students to see the essential and unique features of a corporation business. This visual should help the less able student see the uniqueness of a business corporation.
d. Use slide numbers 8, 9 and 10 from the Slide Set, "Cooperatives and Their Business Neighbors." By careful explanation and discussion with the class, they will be able to see the features of a corporation clearly. Thorough discussion is essential to help the less able student see those points.

12025

6. To understand how cooperative businesses are set up and operated

Cooperatives are planned and developed to meet the needs of certain groups of people. The central concept is a group of people acting together to meet a common need.

As with the regular business corporation, the cooperative business corporation has these features:

a. The cooperative business is a "legal person" in terms of administration and operation under the laws of government.
b. It can sue or be sued in its own name.
c. Its life goes on uninterrupted by the death or withdrawal of members of stockholders.
d. A cooperative needs capital, facilities, and management just as does any business.

Unique features of the cooperative business corporation

a. Cooperatives are primarily to serve their members.
b. Basic policy is determined at general meetings open to all members. Operational policy is set by the board of directors.
c. The members elect a board of directors who make the management decisions.
d. Each member has one vote, regardless of the number of shares of stock he owns. (This is in a pure cooperative.)
e. Excess net margin from the business is returned to the members (owners) as patronage refunds. The size of the refund depends upon the amount of business the member has transacted through the cooperative. Earnings may also be used to pay dividends on stock.

Other characteristics of a cooperative business

a. The members are the owners of the business.
b. Cooperatives pay all taxes as required by law. They do not pay taxes on profits because they are non-profit businesses. Refunds are paid to the members when a profit--net margin--is made. The refund is taxable to the individual member as income.
c. The board of directors hire a manager, who in turn hires the needed staff to run the business.
d. The manager is the key person in any cooperative. He either makes it work, or it fails. He must operate within the guidelines given him by the elected board of directors.
e. Cooperatives tend to increase competition, create bargaining power for groups by offering an alternative place to purchase and to supply needed services not always available from other sources.

12025

12026

Mutual aid among people is as old as man. Economic institutions based on cooperative aid have appeared throughout human history.

a. The earliest cooperatives were groups of primitive people who, together, tended fires and hunted animals they could not possibly kill or face alone.
b. Many of the present aspects of cooperation existed in the Early Greek Era.
c. During the Renaissance, mutual cooperative insurance organizations were organized in London and Paris. The German Landschaften System was an ancestor of the Farm Credit System now in use in the United States.
d. It was during the Industrial Revolution that Modern Cooperation began with the "Society of Equitable Pioneers" in Rochdale, England, in 1844.
e. In the United States, the cooperative enterprise had its beginning with Benjamin Franklin's Fire Insurance Society in Philadelphia in 1752.
f. After the Civil War a notable cooperative movement was that of the Grange.
g. During the Roosevelt New Deal, cooperatives received strong encouragement through federal legislation. Below are some types who began or grew through those years.

(1) Rural Electric Cooperatives - (RECC) (1935)
(2) Farm Supply Purchasing Cooperatives (S.S. Coop)
(3) Federal Land Bank Associations - (FLBA) (1917)
(4) Production Credit Associations - (PCA) (1933)
(5) Artificial Breeding Cooperatives - (KABA)
(6) Milk Marketing Cooperatives - (KYANA)
(7) Farmers Mutual Insurance Companies - (Farm Bureau Mutual)
(8) Commodity Credit Corporation (Tobacco) ("Pool")
(9) Livestock Cooperatives
(10) Others

The specific form of cooperative business organization most common in the world today is one patterned on the "Rochdale Principles."

These were developed by 28 textile workers in Rochdale, England, in 1844. They are:

a. Open membership.
b. Democratic control - (one member--one vote).
c. Limited return on capital.
d. Payment of patronage refunds.

<u>Suggested Teaching-Learning Activities</u>

a. Suggested problem: How do cooperative businesses operate?
b. Invite in a representative of a local cooperative to discuss cooperatives with the class.

12027

c. Using Transparency HS-76-6-1 can help the class visualize the cooperative business. This can be very helpful in teaching something about cooperatives to the less able student, who often has trouble understanding verbal material.
d. Use Transparency HS-76-6-2 to put into a historical frame the origins in the development of our modern cooperatives. Explain this carefully for the benefit of the less able student.
e. Use slide numbers 11 and 12 from the Slide Set, "Cooperatives and Their Business Neighbors." This teaching tool is very specific for this learning, and very valuable for the less able student as it clearly makes some points about the value of cooperative businesses.

Slide numbers 11 and 12 from Slide Set, "Cooperatives and Their Business Neighbors"

7. To know how the member-patron of a cooperative business differs from the customer of a business that is not a cooperative

Factors relating to the cooperative member-patron

a. The member-patron is both an owner and a user of the services.
b. He helps provide capital that the cooperative must have in order for it to do jobs for him that help increase his net income from farming.
c. In a cooperative, members can change things relating to management, etc. This can be done by working through the members of the board of directors.
d. The member-patron is interested in paying a fair price for cooperative goods or services. He is also interested in getting a good price for commodities sold through the cooperative. This is the same goal anyone who is buying or selling tries to achieve from his business dealings.

The law requires a full and complete accounting of the cooperative business to its members at least once a year.

a. This is usually done at the Annual Membership Meeting.
b. The manager, accountant, and others give much of the report, but it is primarily a report of the board of directors to the members as to how they have handled the business of the cooperative.
c. In contrast, the customer of a non-cooperative business gets no accounting of earnings by the business during the year.

Suggested Teaching-Learning Activities

a. Suggested problem: How does a member-patron of a cooperative business differ from a regular business customer?
b. It may be desirable to invite in a representative of a cooperative business to explain to the class the essential differences relating to this learning.
c. The use of Transparency HS-76-7-1 should help clarify these differences. Be sure you thoroughly explain the transparency, as it should help the student understand the material more completely.
d. A blackboard list of "Differences vs Similarities" may be useful here. Allow the class members to complete it, permitting the less able student to participate at the beginning.

8. To make use of farmer cooperatives to increase net farm income

The modern American farmer is more of a specialist in physical production than he is, or can expect to be, in marketing or purchasing. Cooperatives can help him.

a. Cooperative marketing of some crops is the accepted method (tobacco, etc.).
b. The average farmer spends over half his gross income for the purchase of various goods and services needed in farming.

06081

II. GENERAL ORGANIZATION

General Statement of Methods of Instruction

To teach best the variety of skills, the related technical knowledge and the social-industrial relationships needed to equip students entering this trade, many methods of teaching are necessary. Each method had distinctive features that cause its use to be best suited for the teaching of a specific type of skill or knowledge.

In teaching shopwork, the following methods are used:

Demonstration	Individual Projects
Explanation	Directed Technique Study
Visual Aids	Group Projects
Questioning	Problem-Solving Activities
Instruction Sheets	Field Trips

In teaching the related technical knowledge and social-industrial relationships, the following methods are used:

Discussion	Written Reports
Directed Study	Visual Aids
Questioning	Field Trips
Individual Reports	

Time Schedule Allotment

BLOCK I - BASIC ELECTRONICS	468 hours
Unit 1 - Basic Shop Practices	48 hours
Unit 2 - Static and Dynamic Electricity	48 hours
Unit 3 - Electrical Circuits	66 hours
Unit 4 - Instruments and Test Equipment	75 hours
Unit 5 - Electrical Measurement	75 hours
Unit 6 - Electrical Circuit Components	48 hours
Unit 7 - Tubes and Transistors	54 hours
Unit 8 - Electronic Controls	54 hours
BLOCK II - RADIO SERVICING	612 hours
Unit 1 - Audio Amplifier Systems	100 hours
Unit 2 - Radio Circuit Construction and Analysis	85 hours
Unit 3 - Receiver Construction	160 hours
Unit 4 - Receiver Servicing	267 hours
BLOCK III - GENERAL TELEVISION SERVICING	215 hours
Unit 1 - Television Test Instruments	15 hours
Unit 2 - Television Circuit Construction and Analysis	30 hours
Unit 3 - Field Servicing	120 hours
Unit 4 - Color Television Receivers	50 hours

c. Frequently farmers are able, through their cooperatives, to improve the quality of goods or services and also reduce their costs.
d. Cooperative purchasing must be conducted just as efficiently as that of any competing business, if any real economic benefit is to be realized by farmers using the cooperative.

No farmer cooperative can serve its members well unless they use it.

a. Cooperatives are user organizations.
b. As business volume goes up, costs usually come down.
c. Frequently the cooperatives, operating at "actual cost," are able to sell at lower prices than do competing businesses. This is not always the case, but will often prove out this way.
d. Cooperative prices may be much the same as those of competing businesses. The farmer should understand that the picture might be much different if cooperatives were to fade out of the picture.
e. Any farmer cooperative belongs to the farmers who are members of it. They have the legal control of it. No farmer cooperative "belongs to everybody."
f. Cooperatives serve the general public to the extent that service does not detract from its basic aim, serving the membership.

Suggested Teaching-Learning Activities

a. Suggested problem: How make effective use of farmer cooperatives?
b. Use slide numbers 13, 14 and 15 from the Slide Set, "Cooperatives and Their Business Neighbors." These slides should be helpful in summing up the unit, and in pointing our how business (including farming), is dependent on other businesses for their earnings.
c. A field trip to a representative cooperative may be made before or after this learning is complete. It might be desirable to allow the students to formulate their conclusion while visiting the cooperative. Be very careful to point out the features to the less able student so he will be able to participate in the group conclusion at school after the trip.

Evaluation of the Unit

This unit should be evaluated in terms of the objectives the teacher desires to attain. Most of these learnings may be measured in terms of understandings, participation, and attitudes toward businesses in the community. The techniques, aids, and materials should be carefully evaluated after the unit has been completed.

Type of Testing Program Used

More than one instrument is used to determine the effectiveness of teaching and to evaluate the achievement of students in the areas of manipulative skills, related technical knowledge, and social-industrial relationships. These are under the general headings of performance and written tests. One sure way to determine whether a student can do something is to have him actually try to do it. Hence, manipulative skills are tested continually in connection with every job. These tests are referred to as performance. In evaluating total performance, consideration is given to the various elements that are significant in the trade area involved. For example:

Safety
Techniques
Finished Product
Time and Effort Expended
Use and Care of Tools, Equipment, and Materials

The rate of progress in the assimilation of related information is revealed in the ability of the student to apply such knowledge to pertinent jobs and in his achievement on written tests which are given at regular intervals. Written tests may be Objective or Essay in form or a combination of both. Sample tests are included in this course of study in a separate section.

Evaluation of Student Progress

Students progress in the manipulative skills according to their demonstrated ability to meet minimum trade standards. They are required to repeat a job until minimum proficiency is reached before they are permitted to advance to the next job. Their rate of progress and the evaluation of it are recorded on a progress chart.

DATES IN THE HISTORY OF COOPERATIVES

PERIOD OF DEVELOPMENT	NATURE OF DEVELOPMENT
3,000 to 540	Cooperative tenant farming
200 B. C.	Loan Societies
476 to 700	Age of violence, cooperation in monasteries
1750 to 1844	Mutual fire associations were begun in Europe and America. Mercantilism replaced by capitalism in Europe. Capitalism gradually modified
1810	First farmers' cooperatives in USA
1844 to 1894	Modern Era of cooperation began with organization of "Society of Equitable Pioneers" by 28 weavers in Rochdale, England in 1844
1900	Beginning of farmers' marketing cooperatives in the U. S.
1917	Federal Land Banks established
1920-30	Most of the regional agricultural marketing and farm supply regional cooperatives in the U. S. were founded in this decade
1933	Cooperative Farm Credit System, including Federal Intermediate Credit Banks and 13 Banks for Cooperatives established by Acts of Congress
1935	Rural Electrification Administration and beginning of rural electric cooperatives

ABSTRACT - Prepared by the Training Publications Division of the Navy, this training course has been prepared for enlisted men who are studying for advancement to Machinist's Mate First and Machinist's Mate Chief. Contents are: (1) Advancement, (2) Maintenance and Material Management, (3) Turbines, (4) Reduction Gears, (5) Steam-Driven Generators, (6) Heat Exchangers and Air Ejectors, (7) Pumps, (8) Piping and Valves, (9) Distilling Plants, (10) Air Conditioning and Refrigeration, (11) Auxiliary Equipment, (12) Administration, Supervision, and Training, (13) Propulsion Plant Efficiency, (14) Engineering Casualty Control, (15) Inspections and Trials, (16) Ship Repair, and (17) Records and Reports. A training film list is appended. A related document in this issue is available as VT 012 786. (GB)

NAVY TRAINING COURSE NAVPERS 10525-C

PREFACE

This training course has been prepared for men of the Navy and of the Naval Reserve who are studying for advancement to Machinist's Mate First and Machinist's Mate Chief.

As one of the Navy Training Courses, this book was prepared by the Training Publications Division, Naval Personnel Program Support Activity, Washington, D.C., for the Bureau of Naval Personnel. Information provided by numerous manufacturers and technical societies is gratefully acknowledged. Technical assistance was provided by the Naval Ship Systems Command, and the Service School Command and Naval Examining Center, Great Lakes, Illinois.

THE UNITED STATES NAVY

GUARDIAN OF OUR COUNTRY

The United States Navy is responsible for maintaining control of the sea and is a ready force on watch at home and overseas, capable of strong action to preserve the peace or of instant offensive action to win in war.

It is upon the maintenance of this control that our country's glorious future depends; the United States Navy exists to make it so.

WE SERVE WITH HONOR

Tradition, valor, and victory are the Navy's heritage from the past. To these may be added dedication, discipline, and vigilance as the watchwords of the present and the future.

At home or on distant stations we serve with pride, confident in the respect of our country, our shipmates, and our families.

Our responsibilities sober us; our adversities strengthen us.

Service to God and Country is our special privilege. We serve with honor.

THE FUTURE OF THE NAVY

The Navy will always employ new weapons, new techniques, and greater power to protect and defend the United States on the sea, under the sea, and in the air.

Now and in the future, control of the sea gives the United States her greatest advantage for the maintenance of peace and for victory in war.

Mobility, surprise, dispersal, and offensive power are the keynotes of the new Navy. The roots of the Navy lie in a strong belief in the future, in continued dedication to our tasks, and in reflection on our heritage from the past.

Never have our opportunities and our responsibilities been greater.

CHAPTER 1

ADVANCEMENT

This training course is designed to help you meet the occupational qualifications for advancement to Machinist's Mate First Class and Chief Machinist's Mate. Chapters 2 through 17 of this training course deal with the technical subject matter of the Machinist's Mate rating. The present chapter provides introductory information that will help you in working for advancement in rating. It is strongly recommended that you study this chapter carefully before beginning intensive study of the chapters that follow.

REWARDS AND RESPONSIBILITIES

Advancement in rating brings both increased rewards and increased responsibilities. The time to start looking ahead and considering the rewards and the responsibilities of advancement is right now, while you are preparing for advancement to MM1 or MMC.

By this time, you are probably well aware of many of the advantages of advancement in rating—higher pay, greater prestige, more interesting and challenging work, and the satisfaction of getting ahead in your chosen career. By this time, also, you have probably discovered that one of the most enduring rewards of advancement is the personal satisfaction you find in developing your skills and increasing your knowledge.

The Navy also benefits by your advancement. Highly trained personnel are essential to the functioning of the Navy. By each advancement in rating you increase your value to the Navy in two ways. First, you become more valuable as a technical specialist in your own rating. And second, you become more valuable as a person who can supervise, lead, and train others and thus make far reaching and long lasting contributions to the Navy.

In large measure, the extent of your contribution to the Navy depends upon your willingness and ability to accept increasing responsibilities as you advance in rating. When you assumed the duties of an MM3, you began to accept a certain amount of responsibility for the work of others. With each advancement in rating, you accept an increasing responsibility in military matters and in matters relating to the occupational requirements of the Machinist's Mate rating.

You will find that your responsibilities for military leadership are about the same as those of petty officers in other ratings, since every petty officer is a military person as well as a technical specialist. Your responsibilities for technical leadership are special to your rating and are directly related to the nature of your work. Operating and maintaining the ship's main propulsion plants is a job of vital importance, and it's a teamwork job; it requires a special kind of leadership ability that can only be developed by personnel who have a high degree of technical competence and a deep sense of personal responsibility.

Certain practical details that relate to your responsibilities for engineroom administration, supervision, and training are discussed in chapter 12 of this training course. At this point, let's consider some of the broader aspects of your increasing responsibilities for military and technical leadership.

YOUR RESPONSIBILITIES WILL EXTEND BOTH UPWARD AND DOWNWARD. Both officer and enlisted personnel will expect you to translate the general orders given by officers into detailed, practical on-the-job language that can be understood and followed even by relatively inexperienced personnel. In dealing with your juniors, it is up to you to see that they perform their work properly. At the same time, you must be able to explain to officers any important needs or problems of the enlisted men.

YOU WILL HAVE REGULAR AND CONTINUING RESPONSIBILITIES FOR TRAINING. Even if you are lucky enough to have a highly skilled and well trained engineroom force, you will still find that training is necessary. For example, you will

12048

always be responsible for training lower rated men for advancement in rating. Also, some of your best workers may be transferred and inexperienced or poorly trained personnel may be assigned to you. Or a particular job may call for skills that none of your personnel have. These and similar problems require you to be a training specialist who can conduct formal and informal training programs to qualify personnel for advancement and who can train individuals and groups in the effective execution of assigned tasks.

YOU WILL HAVE INCREASING RESPONSIBILITIES FOR WORKING WITH OTHERS. As you advance to MM1 and then to MMC, you will find that many of your plans and decisions affect a large number of people, some of whom are not in the engineroom and some of whom are not even in the engineering department. It becomes increasingly important, therefore, to understand the duties and responsibilities of personnel in other ratings. Every petty officer in the Navy is a technical specialist in his own field. Learn as much as you can about the work of other ratings, and plan your own work so that it will fit in with the overall mission of the organization.

AS YOUR RESPONSIBILITIES INCREASE, YOUR ABILITY TO COMMUNICATE CLEARLY AND EFFECTIVELY MUST ALSO INCREASE. The basic requirement for effective communication is a knowledge of your own language. Use correct language in speaking and in writing. Remember that the basic purpose of all communication is understanding. To lead, supervise, and train others, you must be able to speak and write in such a way that others can understand exactly what you mean.

A second requirement for effective communication in the Navy is a sound knowledge of the Navy way of saying things. Some Navy terms have been standardized for the purpose of ensuring efficient communication. When a situation calls for the use of standard Navy terminology, use it.

Still another requirement of effective communication is precision in the use of technical terms. A command of the technical language of the Machinist's Mate rating will enable you to receive and convey information accurately and to exchange ideas with others. A person who does not understand the precise meaning of terms used in connection with the work of his own rating is at a disadvantage when he tries to read official publications relating to his work. He is also at a great disadvantage when he takes the written examinations for advancement in rating. Although it is always important for you to use technical terms correctly, it is particularly important when you are dealing with lower rated men; sloppiness in the use of technical terms is likely to be very confusing to an inexperienced man.

YOU WILL HAVE INCREASED RESPONSIBILITIES FOR KEEPING UP WITH NEW DEVELOPMENTS. Practically everything in the Navy—policies, procedures, equipment, publications, systems—is subject to change and development. As an MM1, and even more as an MMC, you must keep yourself informed about all changes and new developments that might affect your rating or your work.

Some changes will be called directly to your attention, but others you will have to look for. Try to develop a special kind of alertness for new information. Keep up to date on all available sources of technical information. Information on sources of primary concern to the Machinist's Mate is given later in this chapter.

THE MACHINIST'S MATE RATING

The Machinist's Mate rating is a general rating; there are no service ratings.

Machinist's Mates operate and repair a wide variety of equipment. Those who are assigned to the engineroom (M division), operate and maintain the ship's main engines and associated equipment such as: pumps, distilling plants, compressors, valves, oil purifiers, heat exchangers, governors, reduction gears, and main shafts and shaft bearings.

Machinist's Mates, who are assigned duties other than in enginerooms, maintain and repair machinery such as: steering engines, anchor windlasses, cranes, winches, elevators, laundry and galley equipment, and air conditioning and refrigeration equipment. Machinist's Mates also perform duties in the generation, stowage, and transfer of some industrial gases.

Machinist's Mates are assigned to all types of steam-driven surface ships, and the nature of the duties of a particular MM will depend largely on the type of ship to which he is assigned. The duties of a Machinist's Mate assigned to a tender or repair ship may consist mainly of repairs and services to other ships assigned to the tender or repair ship. A Machinist's Mate may choose a specialized area such as air conditioning and refrigeration or the manufacture of industrial gases. These two fields require special training which he may get in the appropriate schools.

Duty at most shore stations is related to training in your field of specialization. You may be assigned as an instructor either at one of the schools

Performance and written test achievement are interpreted as follows:

A	Outstanding	95 - 100
B	Above Average	85 - 94
C	Average	75 - 84
D	Below Average	70 - 74
F	Unsatisfactory	Below 70

Text and Reference Materials

or at a recruit training station. To qualify for instructor duty you must successfully complete a course in instructor training.

Machinist's Mates may get duty at the Naval Examining Center, Great Lakes, Illinois. Personnel assigned to the Exam Center assist in the preparation of the servicewide examinations prepared for advancement in rating.

Another shore billet for a Machinist's Mate is located at the Training Publications Division, Naval Personnel Program Support Activity, Washington, D.C. Personnel assigned to this activity assist in the preparation and revision of Navy training courses and other training materials.

Other assignments ashore may include attache duty and recruiting duty.

REQUIREMENTS FOR ADVANCEMENT

In general, to qualify for advancement you must:

1. Have a certain amount of time in grade.
2. Complete the required military and occupational training courses.
3. Demonstrate the ability to perform all the PRACTICAL requirements for advancement by completing the Record of Practical Factors, NavPers 1414/1.
4. Be recommended by your commanding officer.
5. Demonstrate your KNOWLEDGE by passing a written examination based on (a) the military requirements for advancement and (b) the occupational qualifications for advancement in the Machinist's Mate rating.

Advancement in rating is not automatic. Meeting all the requirements makes you eligible for advancement but it does not guarantee your advancement. Some of the factors that determine which persons, out of those who take the examination, will actually be advanced in rating are the scores made on the written examination, the length of time in service, the performance marks, and the quotas for the rating.

Remember that the requirements for advancement may change from time to time. Check with your division officer or with your training officer to be sure you have the most recent requirements when you are preparing for advancement and when you are helping lower rated men to prepare for advancement.

To prepare for advancement, you need to be familiar with (1) the military requirements and the occupational qualifications given in the Manual of Qualifications for Advancement in Rating, NavPers 18068-B (with changes); (2) the Record of Practical Factors, NavPers 1414/1; (3) appropriate Navy Training Courses; and (4) any other material that may be required or recommended in the current edition of Training Publications for Advancement in Rating, NavPers 10052. These materials are discussed later in the section of this chapter that deals with sources of information.

SCOPE OF THIS TRAINING COURSE

Before studying any book, it is a good idea to know the purpose and the scope of the book. Here are some things you should know about this training course:

- It is designed to give you information on the occupational qualifications for advancement to MM1 and MMC.

- It must be satisfactorily completed before you can advance to MM1 or MMC, whether you are in the regular Navy or in the Naval Reserve.

- It is NOT designed to give you information on the military requirements for advancement to PO1 or CPO. Navy Training Courses that are specially prepared to give information on the military requirements are discussed in the section of this chapter that deals with sources of information.

- It is NOT designed to give you information that is related primarily to the qualifications for advancement to MM3 and MM2. Such information is given in Machinist's Mate 3&2, NavPers 10524-C.

- The occupational Machinist's Mate qualifications that were used as a guide in the preparation of this training course were those promulgated in the Manual of Qualifications for Advancement in Rating, NavPers 18068-B, change 1. (Change 2, 1967, and change 3, 1968, did not affect the MM qualifications.) Therefore, changes in the Machinist's Mate qualifications occurring after this change may not be reflected in the information given in this training course. Since your major purpose in studying this training course is to meet the qualifications for advancement to MM1 or MMC, it is important for you to obtain and study a set of the most recent Machinist's Mate qualifications.

- This training course includes information that is related to both the KNOWLEDGE FACTORS and the PRACTICAL FACTORS of the qualifications for advancement to MM1 and MMC. However, no

16981 12050

training course can take the place of actual on-the-job experience for developing skill in the practical factors. The training course can help you understand some of the whys and wherefores, but you must combine knowledge with practical experience before you can develop the required skills. The Record of Practical Factors, NavPers 1414/1, should be utilized in conjunction with this training course whenever possible.

- This training course deals almost entirely with the main propulsion plants and associated equipment installed on conventional steam-driven surface ships. It does NOT contain information that is primarily related to nuclear-powered ships, to diesel-driven ships, or to submarines.

- Chapters 2 through 17 of this training course deal with the occupational subject matter of the Machinist's Mate rating. Before studying these chapters, study the table of contents and note the arrangement of information. Information can be organized and presented in many different ways. You will find it helpful to get an overall view of the organization of this training course before you start to study it.

SOURCES OF INFORMATION

It is very important for you to have an extensive knowledge of the references to consult for detailed, authoritative, up-to-date information on all subjects related to the military requirements and to the occupational qualifications of the Machinist's Mate rating.

Some of the publications discussed here are subject to change or revision from time to time—some at regular intervals, others as the need arises. When using any publication that is subject to change or revision, be sure you have the latest edition. When using any publication that is kept current by means of changes, be sure you have a copy in which all official changes have been entered.

BUPERS PUBLICATIONS

The BuPers publications described here include some which are absolutely essential for anyone seeking advancement in rating and some which, although not essential, are extremely helpful.

THE QUALS MANUAL—The Manual of Qualifications for Advancement in Rating, NavPers 18068-B (with changes), gives the minimum requirements for advancement to each rate within each rating. The Quals Manual lists the military requirements which apply to all ratings and the occupational qualifications that are specific to each rating.

The Quals Manual is kept current by means of numbered changes. These changes are issued more frequently than most Navy Training Courses can be revised; therefore, the training courses cannot always reflect the latest qualifications for advancement. When preparing for advancement, you should always check the LATEST Quals Manual and the LATEST changes to be sure that you know the current requirements for advancement in your rating.

When studying the qualifications for advancement, remember these three things:

1. The quals are the MINIMUM requirements for advancement to each rate within each rating. If you study more than the required minimum, you will, of course, have a great advantage when you take the written examination for advancement in rating.

2. Each qual has a designated pay grade—E-4, E-5, E-6, E-7, E-8, or E-9. You are responsible for meeting all quals specified for advancement to the pay grade to which you are seeking advancement AND all quals specified for lower pay grades.

3. The written examinations for advancement to E-6 and above contain questions relating to the practical factors and the knowledge factors of BOTH military/leadership requirements and occupational qualifications. Personnel preparing for advancement to E-4 or E-5 must pass a separate military/leadership examination prior to participation in the Navy-wide occupational examination. The military/leadership examinations for the E-4 and E-5 levels are given according to a schedule prescribed by the commanding officer. Candidates are required to pass the applicable military/leadership examination only once.

A special form known as the RECORD OF PRACTICAL FACTORS, NavPers 1414/1, is used to record the satisfactory completion of the practical factors, both military and occupational, listed in the Quals Manual. Whenever a person demonstrates his ability to perform a practical factor, appropriate entries must be made in the DATE and INITIALS columns. As an MM1 or MMC, you will often be required to check the practical factor performance of lower rated men and to report the results to your supervising officer. To facilitate

12051

record keeping, group records of practical factors are often maintained aboard ship. Entries from the group records must, of course, be transferred to each individual's Record of Practical Factors at appropriate intervals.

As changes are made periodically to the Quals Manual, new forms of NavPers 1414/1 are provided when necessary. Extra space is allowed on the Record of Practical Factors for entering additional practical factors as they are published in changes to the Quals Manual. The Record of Practical Factors also provides space for recording demonstrated proficiency in skills which are within the general scope of the rating but which are not identified as minimum qualifications for advancement. Keep this in mind when you are training and supervising lower rated personnel. If a man demonstrates proficiency in some skill which is not listed in the Machinist's Mate quals but which falls within the general scope of the rating, report this fact to the supervising officer so that an appropriate entry can be made.

The Record of Practical Factors should be kept in each man's service record and should be forwarded with the service record to the next duty station. Each man should also keep a copy of the record for his own use.

NAVPERS 10052.—Training Publications for Advancement in Rating, NavPers 10052, is a very important publication for anyone preparing for advancement in rating. This publication lists required and recommended Navy Training Courses and other reference material to be used by personnel working for advancement in rating. NavPers 10052 is revised and issued once each year by the Bureau of Naval Personnel. Each revised edition is identified by a letter following the NavPers number. When using this publication, be SURE you have the most recent edition.

The required and recommended references are listed by pay grade level in NavPers 10052. It is important to remember that you are responsible for all references at lower pay grade levels, as well as those listed for the pay grade level to which you are seeking advancement.

Navy Training Courses that are marked with an asterisk (*) in NavPers 10052 are MANDATORY at the indicated pay grade levels. A mandatory training course may be completed by (1) passing the appropriate Enlisted Correspondence Course based on the mandatory training course, (2) passing locally prepared tests based on the information given in the mandatory training course, or (3) in some cases, successfully completing an appropriate Navy school.

It is important to notice that all references, whether mandatory or recommended, listed in NavPers 10052 may be used as source material for the written examinations, at the appropriate pay grade levels.

NAVY TRAINING COURSES.—Navy Training Courses are written for the specific purpose of helping personnel prepare for advancement in rating. Some courses are general in nature and are intended for use by more than one rating; others (such as this one) are specific to the particular rating.

Navy Training Courses are revised from time to time to bring them up to date. The revision of a Navy Training Course is identified by a letter following the NavPers number. You can tell whether a Navy Training Course is the latest edition by checking the NavPers number and the letter following the number in the most recent edition of the List of Training Manuals and Correspondence Courses, NavPers 10061 (revised).

There are three Navy Training Courses that are specially prepared to present information on the military requirements for advancement. These courses are:

Basic Military Requirements, NavPers 10054 (current edition).

Military Requirements for Petty Officer 3 & 2, NavPers 10056 (current edition).

Military Requirements for Petty Officer 1 & C, NavPers 10057 (current edition).

Each of the military requirements courses is mandatory at the indicated pay grade levels. In addition to giving information on the military requirements, these three books give a good deal of useful information on the enlisted rating structure; how to prepare for advancement; how to supervise, train, and lead other men; and how to meet your increasing responsibilities as you advance in rating.

Some of the Navy Training Courses that may be useful to you when you are preparing to meet the occupational qualifications for advancement to MM1 and MMC are discussed briefly in the following paragraphs. For a complete listing of Navy Training Courses, consult the List of Training Manuals and Correspondence Courses, NavPers 10061 (revised).

Basic Handtools, NavPers 10085-A. Although this training course is not specifically required for advancement in the Machinist's Mate rating, you will find that it contains a good deal of useful information on the care and use of all types of

12052

handtools and portable power tools commonly used in the Navy.

Blueprint Reading and Sketching, NavPers 10077-B, contains information that may be of value to you as you prepare for advancement to MM1 and MMC.

Mathematics, Vol. 1, NavPers 10069-C, and Mathematics, Vol. 2, NavPers 10071-A. These two training courses may be helpful if you need to brush up on your mathematics. Volume 1, in particular, contains basic information that is needed for using formulas and for making simple computations. The information contained in volume 2 is more advanced than you will need for most purposes, but you may occasionally find it helpful.

Machinist's Mate 3 & 2, NavPers 10524-C. Satisfactory completion of this training course is required for advancement to MM3 and MM2. If you have met this requirement by satisfactorily completing an earlier edition of Machinist's Mate 3 & 2, you should at least glance through the C revision of the training course. Much of the information given in this edition of Machinist's Mate 1 & C is based on the assumption that you are familiar with the contents of Machinist's Mate 3 & 2, NavPers 10524-C.

Navy Training Courses prepared for other Group VII (Engineering and Hull) ratings are often a useful source of information. Reference to these training courses will increase your knowledge of the duties and skills of other men in the engineering department. The training courses prepared for Boilermen, Enginemen, and Boilermakers are likely to be of particular interest to you.

OFFICER TEXTS.—Officer texts that you may find helpful when you are preparing for advancement to MM1 and MMC include Engineering, Operation and Maintenance, NavPers 10813-B; Engineering Administration, NavPers 10858-C; and Principles of Naval Engineering, NavPers 10788-A.

CORRESPONDENCE COURSES.—Most Navy Training Courses and Officer Texts are used as the basis for correspondence courses. Completion of a mandatory training course can be accomplished by passing the correspondence course that is based on the training course. You will find it helpful to take other correspondence courses, as well as those that are based on mandatory training courses. For example, the completion of the correspondence course based on Engineering, Operation and Maintenance is strongly recommended for personnel preparing for advancement to MMC. Taking a correspondence course helps you to master the information given in the training course or text and also gives you a pretty good idea of how much you have learned from studying the book.

OTHER BUPERS PUBLICATIONS.—Additional BuPers publications that you may find useful in connection with your responsibilities for leadership, supervision, and training include the Manual for Navy Instructors, NavPers 16103-C, and the Naval Training Bulletin, NavPers 14900 (published quarterly).

NAVSHIPS PUBLICATIONS

A number of publications issued by the Naval Ship Systems Command will be of interest to you. While you do not need to know everything that is given in the publications mentioned here, you should have a general idea of where to find information in NavShips publications.

The Naval Ships Technical Manual is the basic doctrine publication of the Naval Ships Systems Command. The Manual is kept up to date by means of quarterly changes. All copies of the Manual should have all changes made in them as soon as possible after the changes are received.

Beginning with the quarterly changes dated 15 July 1963, the Naval Ship Systems Command began to renumber individual chapters in the Naval Ships Technical Manual according to the Navy-Marine Corps Standard Subject Classification System. Under this system, all chapters of the Manual will eventually be part of the 9000 series which identifies ship design and ship's material subject groups. When all chapters have been renumbered to conform to the 9000 numbering system, the old chapter numbers will be eliminated. In the meantime, you will have to consult the sheets in the front of the first volume of the Manual which cross-reference the new numbering system and the old. Some of the Manual chapters remain in their old positions, so the new and the old numbers have a definite relationship to each other. For example, the old chapter 51 will in time be renumbered as 9510, and the old chapter 48 will be renumbered as 9480. However, some of the chapters will be moved to new locations, as well as being renumbered; in these cases, there is no clear relationship between the old numbers and the new. For example, the old chapter 6 has been moved to a new location and is now numbered 9004.

The following chapters of the Naval Ships Technical Manual, identified by both old number and new numbers are of particular importance to you.

12053

Chapter Number Old	New	Title
4	9003	Allowances, Surveys, and Requests for Material
6	9004	Inspections, Records, and Reports
20	9200	Winches and Capstans
21	9210	Hydraulic Speed Gears
22	9220	Steering Gear
23	9230	Industrial Gases
39	9390	Thermal Insulation
40	9400	Tables of Technical Data
41	9410	Main Propelling Machinery (Sections I, II, III, and V)
42	9420	Reduction Gears
43	9430	Bearings and Shafting
45	9450	Lubricants and Lubrication Systems
46	9460	Condensers and Air Ejectors
47	9470	Pumps
48	9480	Piping Systems
49	9490	Compressed Air Plants
50	9500	Auxiliary Steam Turbines
58	9580	Distilling Plants
59	9590	Refrigerating Plants
88	9880	Damage Control (Section III, Engineering Casualty Control)
95	9950	Gaskets and Packing

It should be noted that chapters of Naval Ships Technical Manual are referred to throughout this training course by both the old chapter number and the new chapter number. If you have any trouble locating the chapter by the number given in this training course, check the cross-reference sheets given in the front of the first volume of the Naval Ships Technical Manual.

The Naval Ship Systems Command Technical News is a monthly publication which contains interesting and useful information on all aspects of shipboard engineering. The magazine is particularly useful because it presents information which supplements and clarifies information contained in the Naval Ships Technical Manual and because it presents information on new equipment, policies, and procedures.

The manufacturers' technical manuals that are furnished with machinery units and many types of equipment are valuable sources of information on operation, maintenance, and repair. The manufacturers' technical manuals for main propulsion plants and other engineroom equipment are usually given NavShips numbers.

TRAINING FILMS

Training films available to naval personnel are a valuable source of supplementary information on many technical subjects. A selected list of training films that may be useful to you is given in appendix I of this training course. Other films that may be of interest are listed in the United States Navy Film Catalog, NavWeps 10-1-777, published in 1966. This catalog is now listed in the NavSup Forms and Publications Catalog, NavSup 2002, as NavAir 10-1-777. Beginning in 1967, Supplements to the Film Catalog carry the number NavAir 10-1777.

When selecting a film, note its date of issue in the film catalog. As you know, procedures sometimes change rapidly. Thus, some films become obsolete rapidly. If a film is obsolete only in part, it may sometimes be shown effectively if before or during its showing you carefully point out to trainees the procedures that have changed. For this reason, if you are showing a film to train other personnel, take a look at it in advance if possible so that you may spot material that may have become obsolete and verify current procedures by looking them up in the appropriate sources before the formal showing.

12054

CHAPTER 2

MAINTENANCE AND MATERIAL MANAGEMENT (3-M)

Maintenance of ships can be divided into two broad categories: preventive maintenance and corrective maintenance. Preventive maintenance consists of routine shipboard procedures designed to increase the effective life of equipment or forewarn of impending troubles. Corrective maintenance includes procedures designed to analyze and correct material defects and troubles. The main objective of shipboard preventive maintenance is the prevention of breakdown, deterioration, and malfunction of equipment. If, however, this objective is not reached, the alternative objective of repairing or replacing the failed equipment—corrective maintenance—must be accomplished.

Shipboard maintenance programs in the past have varied from one command to another, resulting in various degrees of operational readiness. A relatively new, uniform system of scheduling, recording, reporting, and managing ship maintenance is now in use. This system, the Navy Maintenance and Material Management (3-M) System, is designed to upgrade the operational readiness of ships. The system is introduced in Machinist's Mate 3 & 2, NavPers 10524-C.

Before studying this chapter, a review of that material is recommended.

The 3-M System is not to be considered a "cure-all" for your equipment and maintenance problems. The system does, however, provide a logical, efficient approach to these problems by launching a forthright attack on electrical, mechanical, and electronic disorders. The system also produces a large reservoir of knowledge about equipment disorders, which, when fed back to the appropriate sources for analysis, should result in the distribution of information regarding corrective steps to prevent recurrences.

The 3-M System, like any other system or program, is only as good as the personnel who make it work. Your role in the system as a PO1 or CPO will include the training of lower rated personnel in its use, as well as the scheduling and supervision of maintenance. General information concerning all aspects of the system is included in this chapter but, as a leading petty officer, you should keep abreast of all developments and changes to the system. In addition to the information found in Machinist's Mate 3 & 2, details on the system and changes related to it are available in the Maintenance and Material Management (3-M) Manual, OPNAV 43P2 (revised). Other sources of information include OPNAV Instruction 4700.16 (revised), the Naval Ship Systems Command Technical News, and directives issued by type commanders.

SCHEDULING OF PLANNED MAINTENANCE

The planning and scheduling of planned maintenance is accomplished through the Planned Maintenance Subsystem (PMS). In addition, the PMS defines the minimum maintenance required, controls its performance, describes the methods, materials, and tools to be used, and aids in the detection and prevention of impending casualties. These factors should prove to be a definite asset to the leading petty officer in forecasting future material requirements and in the proper utilization of available manpower.

It should be noted that the PMS does not cover certain operating checks and inspections that are required as a normal part of the regular watchstanding routine. For example, you will not find such things as hourly pressure and temperature checks or routine oil level checks listed as maintenance requirements under the PMS. Even though these routine operating checks are not listed as PMS requirements, you must of course still perform them in accordance with all applicable watchstander's instructions.

The Planned Maintenance Subsystem is based upon the proper utilization of PMS Manuals, Maintenance Requirement Cards (MRCs), and schedules for the accomplishment of planned maintenance actions.

CYCLE SCHEDULE GPMAV FORM 6700-4 (6-61) C-40094

98.172

Figure 2-1.—Cycle schedule.

CYCLE SCHEDULE

Through the use of a cycle schedule (fig. 2-1), the Planned Maintenance Subsystem is designed to simplify the scheduling of planned maintenance. All required planned maintenance actions are programmed throughout the overhaul cycle of a ship. In addition, the system is flexible enough to readily accommodate any changes in a ship's employment schedule.

The cycle schedule contains a list of the components for each division or maintenance group and indicates the quarter after overhaul in which the semiannual, annual, and overhaul cycle, maintenance requirements are to be scheduled. The cycle schedule also lists the quarterly, monthly, and situation requirements that must be scheduled every quarter. The department head, in conjunction with division officers and leading petty officers, uses the cycle schedule in making out the quarterly schedule.

By definition, the day a ship leaves the shipyard is in the first quarter after overhaul. A ship is not necessarily expected to perform all of the planned maintenance listed for the first quarter after overhaul, but the amount performed must be in proportion to the time remaining in that particular quarter. The steps to follow in using the cycle schedule can best be explained by reference to figure 2-1. Consider, for example, the planned maintenance required for the #1 main refrigeration unit. As indicated on the cycle schedule, a short description of the maintenance required may be found on page A-6 of the Planned Maintenance Subsystem Manual. From the cycle schedule, it is apparent that the maintenance must be scheduled as follows:

M 1 and M 2	Each Month
Q 1	Each Quarter
S 1	2nd, 4th, 6th, 8th, 10th, and 12th quarters after overhaul
A 1 and A 2	3rd, 7th, and 11th quarters after overhaul
C 1 and C 2	4th quarter after overhaul (denoted by the numeral "4" in parenthesis on cycle schedule).

QUARTERLY SCHEDULE

The quarterly schedule is a visual display consisting of two identical quarterly schedule forms,

12056

one for the current quarter and one for the subsequent quarter. Figure 2-2 is an example of a quarterly schedule. The cycle schedule and both quarterly schedule forms are contained in the same visual display holder, and correspond line for line. The entire display is called the maintenance control board and is maintained in the departmental office. The maintenance control board shows the overall status of planned maintenance within the department.

The quarterly schedule has thirteen columns, one for each week in the quarter, for scheduling of maintenance throughout the three month period. Each of the weeks is divided into days by tick marks (see fig. 2-2) to depict more accurately the operating schedule, thus allowing maintenance requirements to be scheduled in conjunction with ship's operations.

A suggested procedure for the preparation of a quarterly planned maintenance schedule is to first black out the dates which the ship is expected to be underway during the quarter. Then, with the aid of the cycle schedule and the Planned Maintenance Subsystem Manual, fill out the quarterly schedule accordingly. Monthly planned maintenance requirements should be scheduled at approximately the same time each month and other planned maintenance actions should be scheduled at equal intervals in so far as practical. After the quarterly schedule is completely filled in, it is a good practice to look it over closely to see if the work load is balanced throughout the quarter. If there appears to be less work scheduled during one week of the quarter than the others, some of the maintenance requirements should be rescheduled to balance the work load throughout the quarter.

The quarterly schedule is updated weekly. The leading petty officer of the division or maintenance group will cross out all maintenance requirements which have been accomplished and will circle all requirements which have not been accomplished. All circled requirements are to be rescheduled by drawing an arrow to a later week as indicated in figure 2-2.

The quarterly schedule is kept on board as a record of all completed maintenance actions. This record may be destroyed at the beginning of the second quarter following the next shipyard overhaul period.

WEEKLY SCHEDULE

The quarterly schedule is also used by the leading petty officer of each division or maintenance group to prepare a weekly planned maintenance schedule (fig. 2-3). The weekly schedule is posted in each working space and is used by the leading petty officer to assign specific maintenance tasks to specific personnel.

The weekly schedule provides a list of the components, the appropriate page number of the Planned Maintenance Subsystem Manual, and spaces for the assignment of maintenance tasks to specific personnel. The daily and weekly planned maintenance actions are preprinted on the weekly schedule forms. All other planned maintenance requirements which are to be performed during a specific week are obtained from the current quarterly schedule.

The preparation of a weekly planned maintenance schedule requires you to take into consideration the manpower available, the time involved in each maintenance task, and the ship's operations. In the assignment of specific personnel to maintenance tasks, it must be remembered that the average time required to perform a task, as listed on the Maintenance Index Page and the Maintenance Requirement Card, does not take into account the time required to assemble the tools and materials to do the maintenance action nor the time required to clean the area and put away the tools at the end of the task. Therefore, related maintenance requirements which are due should be scheduled and performed together to conserve time. Any corrective maintenance, cleaning, and upkeep to be performed is in addition to the planned maintenance prescribed by the Planned Maintenance Subsystem.

The weekly schedule offers flexibility for all planned maintenance actions except those which must be performed daily. When a planned maintenance task is completed, the leading petty officer will cross out the requirement on the schedule. Maintenance that cannot be completed on schedule is circled and rescheduled on the basis of workload and the ship's operations.

The weekly schedule is designed for convenient preparation and effective reuse. At the end of each week, the leading petty officer of the division or maintenance group will take the weekly schedule to the departmental office, update the quarterly schedule, erase the plastic-covered weekly schedule, and prepare a schedule for the following week.

RECORDING OF MAINTENANCE ACTIONS

The Maintenance Data Collection Subsystem (MDCS) is designed to provide a means of recording information concerning planned and corrective

Figure 2-3.—Weekly schedule.

maintenance actions. Maintenance performed is recorded by code in sufficient detail to permit the collection of a great variety of information concerning maintenance actions and the performance of the equipment involved. The use of codes in recording and reporting maintenance actions permits machine processing with automatic data processing equipment. The system also provides data concerning the initial discovery of a malfunction, how the equipment malfunctioned, how many hours the equipment was in operation, which equipment was involved, what repair parts and materials were used, what delays were incurred, the reason for delay, and the technical specialty or work center which performed the maintenance. Each maintenance action is reported in this manner except for routine preservation actions (chipping, painting, and cleaning) and daily or weekly maintenance actions.

The shipboard installation of the Maintenance Data Collection Subsystem includes a central, functional data collection center. The primary function of the shipboard data collection center is to screen all documents for completeness and accuracy before they are forwarded to the data processing center. During the screening process, the data collection center adds a four-digit maintenance control number to each document unless the person doing the task has already received and entered a maintenance control number to obtain parts or materials from the supply department.

The effectiveness of the Maintenance Data Collection Subsystem depends initially upon the individual performing the maintenance action and the accuracy with which it is reported. Leading petty officers are responsible for ensuring that all forms used in connection with the Maintenance Data Collection Subsystem are complete and accurate. Leading petty officers must also ensure that a form is submitted for each applicable action and that no action is reported more than once.

EQUIPMENT IDENTIFICATION CODE MANUAL

It is essential that all personnel having any responsibility for maintenance actions be indoc-

Reaming	Selection and use of reamers

1204
1203

trinated in the proper use of the Equipment Identification Code Manual as it contains many codes used in the reporting of maintenance actions. Each major system is coded and the codes are broken down to the lowest part necessary for positive equipment identification. The manner in which the equipment identification code is obtained from the manual is described in the following example.

Assume it is desired to determine the code for the casing wearing rings and impeller wearing rings of a main condensate pump in the main steam propulsion system. By referring to the index pages (section X) of the Equipment Identification Code Manual, it is found that the MAIN PROPULSION SYSTEM, STEAM is identified by the code "Z" and the index page will be X - Z - 1 or 2. By referring to page X - Z - 1, the subsystem (in this case the feed and condensate system) is identified by the code "ZQ". The next step is to turn to the pages of the manual with the ZQ codes and go down the list of equipment until you come to the listing for the main condensate pump. Under this listing you will find the 7-digit codes for the casing wearing rings and impeller wearing rings. The first digit of the code identifies the system, the second digit identifies the subsystem, the third and fourth digits identify the equipment, and the last three digits identify the assembly. If the assembly requires further breakdown, the last digit identifies the subassembly.

In addition to the equipment identification codes, the Equipment Identification Code Manual contains other codes and information of equal importance to the equipment identification codes. Section I of the manual contains general instructions for the preparation of forms when reporting maintenance actions. Other sections of the manual contain additional codes as follows:

Section II	Administrative Organizations
Section III	Work Centers
Section IV	How Malfunctioned
Section V	When Discovered
Section VI	Action Taken
Section VII	Service
Section VIII	Source
Section IX	Type Availability

These codes make possible the recording of a wide variety of information in a relatively small space. At the data processing level, the codes permit use of automatic data processing operations which provide pertinent direct reading information summaries. The summaries can be profitably employed only if accurate information has been recorded; therefore, familiarity with the coding system is a must and the importance of accuracy in the recording of codes must be continually stressed.

MDCS DOCUMENTATION

Documentation in the Maintenance Data Collection Subsystem is accomplished by the completion, as applicable, of one or more standard forms. Forms used to record and report information related to maintenance actions aboard ship and within repair activities include, OPNAV Form 4700-2B (Shipboard Maintenance Action), OPNAV Form 4700-2D (Deferred Action), and OPNAV Form 4700-2C (Work Request). Detailed descriptions of the entries to be made on these forms are listed in Section I of the Equipment Identification Code Manual and in chapter 3 of the Maintenance and Material Management (3—M) Manual, OPNAV 43P2.

Shipboard Maintenance Actions

A sample Shipboard Maintenance Action Form (OPNAV 4700-2B) is shown in figure 2-4. This form is a single-sheet document used to record the completion of planned maintenance actions, corrective maintenance actions, and authorized alterations that have been performed at the shipboard level by shipboard personnel. All planned maintenance actions except daily and weekly actions must be recorded on this form. Routine preservation such as chipping, painting, and cleaning should not be reported.

The Shipboard Maintenance Action Form is also used to report work done aboard ship by an outside activity which does not report under the Maintenance Data Collection Subsystem. When a repair activity such as a civilian contractor or a shipyard (except for regular overhauls) which is not under the Maintenance Data Collection Subsystem provides ship maintenance assistance, duplicate 4700-2B documents are prepared. Block 7 of the original document is left blank and the code for the assisting work center is entered on the duplicate. Only those manhours actually spent by the shipboard personnel in assisting the outside activity are entered in block 13 of the original; manhours spent by the outside activity in assisting the shipboard work center are documented in block 13 of the duplicate.

Deferred Actions

The Deferred Action Form (OPNAV 4700-2D) is a two-sheet form used to report corrective maintenance actions that are deferred because of

the ship's operations, the lack of repair parts, or the requirement for outside assistance. The first sheet (fig. 2-5) is used to record and report the reason for deferral and the second sheet (fig. 2-6) is used to report the completion of the deferred action.

If a corrective maintenance action is beyond ship's force capability and outside assistance is required, a work request is prepared and forwarded. This situation will always require that an OPNAV Form 4700-2D be submitted. The manhours that have been expended by the ship's force in connection with the maintenance action, even if they consist of only the time required to fill out the form, are documented on the OPNAV Form 4700-2D. The manhours involved in the investigation and the removal of the equipment are documented on the first sheet of the form. The manhours involved in the reinstallation of the equipment are documented on the second sheet when the task is completed.

If a shipboard maintenance action must be deferred due to the lack of necessary repair parts or because of the ship's operations, an OPNAV Form 4700-2D is prepared and the first sheet is submitted using the appropriate action taken code from section VI of the Equipment Identification Code Manual and the manhours expended are entered in block 13. When the maintenance action is completed, the second sheet is submitted using the appropriate action taken code and the manhours expended in completing the action are entered in block 13.

Work Requests

The Work Request (OPNAV 4700-2C) is a four-sheet document which is presently used to request outside assistance from repair ships and tenders. Part I of the Work Request is shown in figure 2-7. Part II of the form is shown in figure 2-8, and is a continuation of Part I to provide additional space for written descriptions, diagrams, or sketches.

The information to be given in block F (Description/Remarks) of the work request includes the name of the component, the CID/AN number of the component, and the alteration number. If the alteration number is not applicable, it must be listed as N/A. Block F should also contain a description of the existing defects, the repairs required on the component and all other information as required by the Type Command.

Sheet 1 of the work request is retained by the requesting activity and sheets 2, 3, and 4 are forwarded to the assigned repair activity via the designated chain of command. Information concerning the administrative procedures to be taken on a work request by repair activities may be found in chapter 4 of the Maintenance and Material Management (3—M) Manual, OPNAV 43P2.

When the work request is accepted by the repair activity, sheet 3 of the document is used as a job order and is sent to the assigned work center. Prepunched Work Supplement Cards (OPNAV 4700-2F) are also sent to the assigned work center. A sample OPNAV 4700-2F is shown in figure 2-9.

The assigned work center performs the job, records the maintenance data on the Work Supplement Cards, and records the material obtained outside of normal supply channels on the reverse side of the card. If more than one work day is required to complete the action, or if assisting work centers are needed, the lead work center will utilize the additional Work Supplement Cards provided to record daily manhours expended. (The lead work center is that work center which has the primary responsibility for the completion of the task described on the work request.)

When a repair job is completed, sheet 3 of the work request is completed by the lead work center and is signed by the man who performed the maintenance. An inspector from the requesting activity is contacted for final inspection and signs off the work request. After obtaining the signature of the inspector, the lead work center supervisor forwards the completed work request to his division officer.

MANHOUR ACCOUNTING SYSTEM

The Manhour Accounting System, sometimes referred to as Exception Time Accounting (ETA), is designed and intended for use by the repair department of a repair activity in conjunction with the Maintenance Data Collection Subsystem. It is basically a management tool and accounts for deviations from a normal seven-hour working day.

12064

Exception Time Accounting includes the use of codes, the preparation of a Master Roster Listing, and the preparation and submission of Daily Exception Cards (OPNAV Form 4700-2E). A sample Daily Exception Card is shown in figure 2-10. Detailed procedures for the use of the card may be found in chapter 5 of the Maintenance and Material Management (3—M) Manual, OPNAV 43P2.

CHAPTER 3

TURBINES

Reliability is the paramount requirement of naval propulsion plant installations. If a ship is to be ready at all times for unlimited operations, the main units of the propulsion machinery, such as turbines, must constantly receive the best of care in operation, maintenance, and repairs.

This chapter presents selected information on operation, maintenance, and repairs of the most common types of main turbines. The MMC or MM1 should refer to the manufacturer's technical manuals and detail drawings in connection with inspection and repair of turbines. The manufacturer's recommendations regarding operation and methods of assembling and fitting parts should be followed whenever practicable. NavShips Technical Manual, chapter 9410 (41), contains information of a more general nature about turbines.

TYPES OF TURBINES

There are various types of turbines installed on naval ships; six major types are:

1. Type I (single-casing unit).—The Type I propulsion unit consists of one or more ahead elements, each contained in a separate casing and identified as a single-casing turbine. Each turbine delivers approximately equal power to a reduction gear.

2. Type II-A (straight-through unit).—The Type II-A propulsion unit is a two element straight-through unit, and consists of two ahead elements, known as a high pressure (HP) element and a low pressure (LP) element. The HP and LP elements are contained in a separate casing and are commonly known as the HP and LP turbines, respectively. The HP and LP turbines deliver power to a single shaft through a gear train and are coupled separately to the reduction gear. Steam is admitted to the HP turbine and flows straight through the turbine axially without bypassing any stages (there is partial bypassing of the first row of blades at high power), and then is exhausted to the LP turbine through a crossover pipe.

3. Type II-B (EXTERNAL bypass unit).—The Type II-B propulsion unit is similar to the Type II-A, except that provision is made for bypassing of steam around the first stage or first several stages of the HP turbine at powers above the most economical point of operation. Bypass valves are located in the HP turbine steam chest, with the nozzle control valves.

4. Type II-C (INTERNAL bypass unit).—The Type II-C is similar to the Type II-A, except that provision is made for bypassing steam from the first-stage shell around the next several (one or more) stages of the HP turbine at powers above the most economical point of operation. Bypass valves and steam connections are usually integral with the HP turbine casing; however, some installations have the valves separate, but bolted directly to the casing, with suitable connecting piping between the first-stage shell and valve to the bypass belt.

5. Type III (series-parallel unit).—The Type III propulsion unit consists of three ahead elements, known as the HP element, intermediate pressure (IP) element, and LP element. The HP and IP elements are combined in a single casing, and known as the HP-IP turbine. Steam is admitted to the HP-IP turbine and exhausted to the LP turbine through a crossover pipe. For powers up to the most economical point of operation, only the HP element receives inlet steam, with the IP element being supplied in series with steam from the HP element exhaust. At powers above this point of operation, both elements receive inlet steam in a manner similar to that in a double-flow turbine. During ahead operation no ahead blading is bypassed. Series-parallel units are being used on some of the more recent naval combatant vessels, such as DEs, DDs, and CVAs.

12066

6. Type IV (cruising geared and vented unit).—The Type IV propulsion unit consists of a cruising element, HP element, and LP element—each contained in a separate casing. The cruising turbine is connected in tandem through a cruising reduction gear to the forward end of the HP turbine. The cruising turbine contributes power to the propeller shaft for powers up to the most economical point of operation, and for higher powers it is idled in a partial vacuum and supplied with cooling steam to prevent overheating. For cruising power, steam is admitted to the cruising turbine and then exhausted to the HP turbine inlet, and thence from the HP turbine exhaust into the LP turbine through a crossover pipe. The arrangement of the HP and LP turbine is identical to the Type II units. It is possible to disconnect the cruising turbine to allow for repair. Once disconnected, the HP turbine may be placed in service.

All of these six types of propelling units contain an astern element for backing or reversing. An astern element is located in each end of a double flow LP turbine casing or can be in either end of each single-casing turbine or single flow LP turbine.

Another classification which affects turbine life requirements and construction is:

Class A—Turbines for use in naval submarines.
Class B—Turbines for use in naval surface ships (warships, mine warfare ships and patrol ships).
Class C—Turbines for use in naval ships (amphibious warfare ships and auxiliary ships).

TURBINE OPERATION

When the turbines are started from a cold condition they are subject to expansive movements due to the temperature of the incoming steam. Exercise care in warming up the unit in order to ensure uniform heating of the components of the turbines. While the turbines are warming up, inspect for proper axial rotar position, freedom from rubbing, correct oil flow to bearings, and effective gland sealing.

Maximum economy is obtained from turbine installations by various means: (1) by the use of cruising turbines, (2) by having cruising stages built into the high pressure turbine, or (3) by hand-controlled nozzle valves. Information on cruising turbines and cruising stages can be found in chapter 3 of Machinist's Mate 3 and 2, NavPers 10524-C.

On some auxiliary ships, hand-controlled valves are used to control the number of nozzles used to admit steam to various stages of the high pressure turbine. By the use of a minimum number of nozzles necessary to deliver the required speed, it is possible, for any given speed (power), to maintain nearly full designed steam pressure on the nozzles in use. In addition to operating the nozzles at their most optimum pressure, the throttling loss is reduced to a minimum because there is practically no pressure drop across the throttle valve. Minor variations in speed within any nozzle combination are, however, taken care of by the throttle valve. Although many auxiliary ship turbines use hand-controlled inlet nozzles, some (reaction) turbines in service incorporate stage bypass valves for high speed operation. Optimum positioning of valves is associated with the use of first stage shell pressure as the operating criteria.

Modern plant installations incorporate the operation of opening and closing nozzle control valves, and bypass valves on a single camshaft. Where nozzle control valves are cam-operated, the throttle valve is omitted; however, in such cases, the control wheel for the cams is usually referred to as the "throttle."

LUBRICATION OF TURBINES

One of the more important factors in the operation and maintenance of main turbines is an adequate supply of lubricating oil having the correct physical and chemical qualities. The main lubricating oil system serves (1) to provide a continuous supply of oil to turbine and reduction gear bearings at the temperature for proper lubrication of the bearings; (2) and to remove heat generated in the bearings.

Turbines are provided with one of the following: (a) NEEDLE VALVES that permit adjustment of the oil flow to all journal and thrust bearings, (b) NONADJUSTABLE ORIFICES in the oil supply lines to each journal bearing, (c) a NONADJUSTABLE ORIFICE in the inlet to or discharge from each thrust bearing, or (d) BEARINGS so constructed that the oil clearance around the journal acts as an orifice. The needle valves are adjustable but the setting should never be changed except in an emergency, and then only by experienced

personnel. These valves are so constructed that they cannot fully cut off the flow of oil to the bearing. With the needle valves properly set, the oil flow to the bearings is such as to provide adequate lubrication, but if a bearing is wiped to such an extent that the oil flows freely out of the sides of the bearing, its needle valve will not permit the damaged bearing to take an excessive amount of oil away from the others.

Under normal operating conditions, the temperature of the oil leaving the lube oil cooler should be between 120° F and 130° F. The outlet temperature of the bearing should be about 140°-160° F but never greater than 180° F. The maximum temperature rise allowable in the bearing (oil) is 50° F, even though such a rise may cause a final temperature of lower than 180° F.

Various means are provided for maintaining a continuous check on the supply of oil to the bearings, and on the bearing temperature as indicated by the temperature of oil flowing from the bearings. On some older installations, a pressure gage is connected to the oil supply line to each bearing, or a spinner-type flow indicator is connected in the supply line. A thermometer is fitted in each bearing as near as possible to the point from which the oil drains from the bearing shell. On modern ships, journal bearings and thrust bearings have four types of temperature indicators presently being used: the mercury bulb thermometer, the bimetallic thermometer, the thermocouple, and the resistance thermometer element (RTE).

The bimetallic thermometer uses the principle of operation that two dissimilar metals expand differently or unequally when heated, and indicates the temperature on a calibrated gage. The bimetallic thermometer can be used to replace the mercury bulb thermometer for direct reading.

Thermocouples have been installed in some bearings to indicate the temperature of the babbitt material. The thermocouples are monitored automatically by an electrical scanning device or monitor, briefly described as follows: The thermocouples are connected to lamps and an alarm in the scanner through contacts. These contacts are made and broken by a rotary stepping switch pulsing circuit which provides the power pulses to operate the rotary stepping switch so that all thermocouple channels can be scanned within 10 seconds. Should the temperature on any bearing exceed 250° F, the lamp corresponding to the bearing will light and the alarm will sound. The alarm may be reset manually, but the light will remain on until the temperature returns to normal. Provision is also made for a meter in the scanner which can be connected to read the actual temperature on any one bearing at a given time.

It should be understood that there will ordinarily be some difference between the temperatures as indicated by the mercury bulb or bimetallic thermometers (where installed) and the scanner meter. These temperatures, however, are due primarily to the difference in position of the sensing elements for the bearing. If the temperature, as read by the thermometer or scanner, should suddenly rise without there having been a change in speed, there may be a distressed bearing, and the speed should be reduced, if possible, and the cause ascertained.

The RTE is an electrical resistance type thermometer installed within the bearing and used to measure the temperature of the babbitt material. The RTE uses the same type monitoring system as the thermocouple.

The bearings and gears of a modern warship require a high grade mineral oil (2190 TEP). The oil must be kept free from water and impurities by means of the purifier and the settling tank. In keeping a continuous check on the condition of the lubricating oil, a routine procedure of taking oil samples should be followed. In addition, the oils should be tested at regular intervals whenever shore testing facilities are available, to determine the neutralization number, flash point, viscosity, and other physical or chemical properties which govern the effectiveness of oil as a lubricant. When operating the turbines, do not rotate the turbines with a lube oil temperature below 90° F except in an emergency. Operate the lube oil purifiers at least 12 hours per day when the ship is under way.

PROCEDURES FOR AN OVERHEATED BEARING

The rotor of every turbine must be supported in bearings, which serve the double purpose of carrying the weight of the rotor and maintaining the correct radial clearances between rotor and casing. All main turbines have a journal bearing at each end of the rotor, and a thrust bearing, to maintain correct axial clearances, usually at the forward end. Modern naval ships have adjustable spherically seated, self-aligning journal bearings and pivoted-shoe type thrust bearings.

Bearing temperatures depend on the viscosity of the oil being used, the design of the bearing,

the running speed, and the oil clearances. Watchstanders should be familiar with the normal operating temperatures of all bearings in their respective spaces. Watchstanders should also understand the precautions and procedures to prevent possible bearing troubles, and what procedures to follow when bearing troubles do occur.

Generally a hot bearing may be traced to one of the following causes:

1. Improper or insufficient lubrication.
2. Grit or dirt in the lubricant.
3. Bearing out of alignment.
4. Bearing improperly fitted.
5. Poor condition of bearing or journal surface.
6. Obstruction in the oil lines.

If the temperature of a bearing increases above its normal running temperature, the quality and quantity of the lubricant supplied to that bearing should be checked immediately. If the trouble is due to improper or insufficient lubrication, and is discovered before the metal has wiped, an abundant supply of lubricant should gradually bring the bearing back to its normal operating temperature. Should the trouble be caused by grit or dirt in the bearing, an increased supply of lubricant may flush out the impurities sufficiently to permit continued operation. The supply of oil should be increased by opening the needle valve, if a needle valve is provided, or by increasing the delivery pressure of the oil pumps, where practicable. The lubricants should be further cooled by increasing the flow of circulating water through the oil cooler. If these measures are not effective, the speed of the unit should be reduced or stopped. Spraying water on a bearing should not be resorted to except in an emergency, as cold water causes contraction of the bearing, further reducing the clearance, and may cause the bearing caps to become distorted.

If the bearings are out of alignment, improperly fitted, or bearings and journals are not in proper condition, the only effective treatment is to operate the turbine at low speed until such time as the proper adjustments or repairs can be made.

The most effective treatment of a hot bearing will probably be the operation of the turbine at low or moderate power. Usually an abnormal temperature in a bearing can be lowered by decreasing the amount of work of the bearing. The temperature of a bearing should never be allowed to exceed 250°F nor the oil return from the bearing allowed to exceed 180°F, since the babbitt will become soft and the bearing will wipe.

If the temperature of a bearing does exceed the maximum allowed, the turbine should be immediately slowed down. The turbine should be kept turning at a minimum speed to prevent the molten metal from adhering to the journal. When the temperature drops below the maximum allowable, the turbine should be stopped, the main shaft locked, and the lubrication system kept in operation.

Bearing depth gage readings should be taken to determine if any wear of the bearing has occurred. If the readings indicate no wear of the bearing, operation of the turbine at low speeds can be attempted, or the bearing can be disassembled for a complete inspection. If the bearing readings show that abnormal wear has occurred, the bearing must be disassembled for repair. Operation of a wiped bearing can result in serious damage to the turbine.

When a bearing overheats, the lube oil strainers should be carefully checked for traces of babbitt. The lube oil should be inspected and the purifier started.

In recent years, the pivoted-shoe type bearing has been adapted to journal bearings. If the shoes are properly pivoted, they will have a freedom of motion which permits them to automatically align themselves to the shaft, and yet hold the shaft to a smaller amount of motion than do sleeve bearings.

ABNORMAL NOISE OR VIBRATION

Turbine rotors shall not be permitted to remain at rest for a period longer than 5 minutes while steam, including gland steam, is being admitted to the turbine. In ships having turning gear, this gear shall be rolling the turbine rotor before steam is admitted to the turbine glands. Turbines not provided with turning gear shall commence

12069

spinning operations as soon as gland steam is admitted to the turbine. Maintain a vacuum of about 25 inches of mercury by using the second-stage air ejector during warmup. Higher vacuum during the warming-up period will retard heating and may cause distortion due to uneven temperatures.

If the rotor and casing are not evenly heated, unequal expansion, resulting in the distortion of the rotor or the casing or both, will take place. The results of this distortion are very noticeable in large turbine installations. Unless extreme care is taken to warm up the turbine properly, serious damage will be done.

If at any time while the turbine is in operation it suddenly begins to vibrate abnormally, the trouble may generally be traced to any one or a combination of the following troubles:

1. Water in the turbine.
2. Bearing failure.
3. Bent or broken propeller blades.
4. Broken or missing turbine blades or rubbing of blades.
5. Rubbing of carbon packing, labyrinth packing, or oil seal rings.
6. Bowed rotor.
7. Excessive differential expansion between rotor and casing.

If a rumbling sound is heard from the turbine when it begins to vibrate, the trouble is probably due to water or foreign matter in the turbine. Water in the turbine casing may be caused by either boiler priming or improper casing and steam line drainage. The turbine should be immediately slowed down until the abnormal noise disappears. If, after slowing down, correcting boiler operation and checking casing and HP drains, the vibration still exists, the turbine shall be shut down and the interior of the turbine shall be inspected at the earliest opportunity. If a sharp metallic sound is heard after the rumbling noise, it may be assumed that the thrust bearing has failed and part of the blading has been damaged.

When bearing troubles occur, the turbine should be stopped as soon as practicable to prevent damage to the turbine blading. The bearings should be inspected, and replaced or repaired as necessary. The cause of the trouble should be determined and appropriate steps should be taken to prevent similar troubles from recurring.

Rubbing of labyrinth or carbon packing or oil seal rings is usually caused by one of the following:

1. Excessive bearing wear.
2. Bowed rotor.
3. Improper installation of packing rings or oil seals.
4. Excessive differential expansion between rotor and casing.

Rubbing of shaft packing or oil seal rings will cause the shaft to overheat in the rubbing area, due to friction; and the shaft will start to show heating discoloration. An immediate inspection should be made to determine the cause of the trouble. If defective bearings are found, they should be replaced. A bowed rotor can be straightened by operating the turbine at low speeds. The shaft packing or oil seals may require refitting or renewal to give proper clearances.

It is also possible for the gland sealing system to cause the seal casing to become "egg" shaped and to cause vibration. This occurs when the turbine is operating at a speed sufficient to permit self-sealing and is slowed to a point where external gland sealing steam is required. When the engine is operating self-sealing, moisture may collect in the external gland seal supply piping if it is not draining properly through the LP drain traps. When the external gland seal supply valve opens, the accumulated condensate is forced into the shaft seal area, causing rapid cooling and distortion. This problem can be prevented by proper drainage of the gland seal line.

When rubbing of turbine blading occurs, the cause will probably be a bowed rotor, a defective thrust bearing assembly, a wiped journal bearing, foreign material inside the casing, or differential expansion of turbine rotor and casing. When a rubbing noise in a turbine is heard, the turbine should be stopped immediately and the cause of trouble determined.

When warming up a turbine, or after a turbine has been warmed up, a vacuum shall not be maintained on the turbine unless the glands are properly sealed. Air leaking in along the shaft, particularly when standing still, tends to cause distortion of the shaft and rotor. If the rotor becomes distorted while standing by, close the drains to the condenser and bring the pressure of the gland steam to between 1/2 and 2 psi above atmospheric pressure, and spin the rotor alternately astern and ahead.
